Anchorage, Alaska 99513-7589

Alaska State Library
State Office Building, 8th Floor
333 Willoughby Avenue
Juneau, Alaska 99811-0571

This publication released by the Division of Geological & Geophysical Surveys, was produced and printed in Fairbanks, Alaska by Date Line Copies, at a cost of \$22 per copy. Publication is required by Alaska Statute 41, "to determine the potential of Alaskan land for production of metals, minerals, fuels, and geothermal resources; the location and supplies of groundwater and construction materials; the potential geologic hazards to buildings, roads, bridges, and other installations and structures; and shall conduct such other surveys and investigations as will advance knowledge of the geology of Alaska."

Cover: View southeast of Homer Spit, a submarine moraine complex formed by grounding of the tidal glacier that occupied Kachemak Bay during the Skilak stade of the Naptowne glaciation. Photograph 137-9 taken June 25, 1990, by R.D. Reger.

CATALOG AND INITIAL ANALYSES OF GEOLOGIC DATA RELATED TO MIDDLE TO LATE QUATERNARY DEPOSITS, COOK INLET REGION, ALASKA

by

Richard D. Reger,¹ DeAnne S. Pinney,² Raymond M. Burke,³ and Milton A. Wiltse²

INTRODUCTION

This Report of Investigations catalogs geologic field and laboratory data accumulated during Alaska Division of Geological & Geophysical Surveys (DGGs) studies of middle to late Quaternary sediments in the Cook Inlet region and presents initial interpretations of these data. This information and the associated geologic mapping (Reger, 1977, 1978a,b and 1981a-d; Reger and Carver, 1977 and 1978a,b; Daniels, 1981a,b; Cameron and others, 1981; Updike and Ulery, 1983a,b and 1986; Rawlinson, 1986; Combellick and Reger, 1988; Reger and Petrik, 1993; and Reger and others, 1994a-d) are the foundations for summaries of the glacial history of the Cook Inlet region by Reger and Updike (1983a,b), Reger (1985), Reger and others (1995), and Reger and Pinney (1996).

DATA PRESENTATION

Sample sites of DGGs and others are tied by index numbers to base maps of the Anchorage, Kenai, Seldovia, Seward, and Tyonek Quadrangles (sheets 1-5) in table 1, which provides latitude and longitude locations for each sample site. Seventy-eight stratigraphic sections and seven soil profiles are illustrated and briefly described in appendix A.

RADIOCARBON DATES

Stratigraphic context and temporal significance of 104 radiocarbon dates in the Cook Inlet region are summarized in table 2; these dates are from both published and unpublished sources. In some instances, we offer interpretations of dates that differ from the interpretations of previous authors to reflect either advances in our knowledge of the glacial history or differences of opinion. Our set of radiocarbon dates is trimodal (fig. 1) and includes: (a) a subset of dates of terrestrial materials between 6,000 and 13,750 ¹⁴C yr B.P. (n = 64); (b) a subset of dates of glaciomarine or glacioestuarine macrofossils between

13,500 and 16,500 ¹⁴C yr B.P. (n = 19); and (c) a subset of infinite dates for reworked wood and lignite of Tertiary age or coal-contaminated organic silt in the Kenai Lowland (n = 8) and infinite dates for the Goose Bay peat or correlative peats in the Anchorage Lowland (n = 13).

Among the terrestrial samples, the oldest surface peat (collected by Karlstrom in the East Foreland area) dates 13,500 ± 400 ¹⁴C yr B.P. (table 2, C64). The oldest finite date is 16,480 ± 170 ¹⁴C yr B.P. for plates of *Balanus evermanni* collected at the mouth of Kenai River (table 2, C83).

Our repeated attempts to date the Goose Bay peat at its type locality on the west side of Knik Arm (Karlstrom, 1964) (table 1, locality ANC-22 and fig. A3) by the radiocarbon method merely duplicated the infinite dates previously published by Karlstrom (1964). However, with a radiocarbon-enrichment age of >73,400 ¹⁴C yr B.P. (table 2, C104) we push the minimum age of the Goose Bay peat back in time 28,400 ¹⁴C yr farther than the oldest date previously documented (Reger and Updike, 1983a, fig. 106).

TEPHRA STUDIES

During our field investigations, volcanic-ash layers were encountered in nearly every excavation, and tephras were sampled at 59 localities (table 1). We did not sample the widespread, unnamed tephra complex in and just beneath the surface organic material primarily because it provides little chronological information for the glacial story and it is undoubtedly composed of the distal airfall products of several historic and prehistoric eruptions from a variety of volcanoes, including Mt. Katmai, Mt. Augustine, Mt. Redoubt, Mt. Spurr (Crater Peak), and Hayes volcano (Wilcox, 1959; Riehle, 1983, 1985, 1994; Riehle and others, 1981, 1990; Kienle and Nye, 1990; Begét and others, 1991, 1994; Begét, Reger, and others, 1991; Begét and Kienle, 1992; Begét and Nye, 1994; Combellick and Pinney, 1995).

METHODOLOGY

The stratigraphic context of the various tephras was documented in the field (app. A), and the glass components of potentially significant volcanic ashes were cleaned and concentrated in the DGGs sediment laboratory using the methods described by Pinney (1991). (*Text cont'd. p. 25*)

Table 1. Relation of map index numbers (sheets 1-5) to field site numbers, stratigraphic sections, radiocarbon samples, tephra samples, magnetic-susceptibility samples, pebble collections, fossil collections, and soil profiles in the Cook Inlet region. Latitudes and longitudes were provided in original sources or determined by digitizing locations on 1:250,000-scale topographic maps and are estimated to be accurate to within 5 seconds. Microprobe geochemistry of tephra samples with asterisk(*) numbers not reported because of great variation

Map index number	Latitude	Longitude	Field site number	Stratigraphic section	Radiocarbon sample	Tephra sample	Magnetic-susceptibility sample	Pebble collection	Macrofossil collection	Soil profile

*Location of C82 is tentative because precise latitude and longitude were not provided by Schmoll and Yehle (1983; 1986, locality B7) or Schmoll and others (1984, locality B4). The site indicated is the only section along Kalifornsky beach where we found *Balanus* plates in Bootlegger Cove Formation.

Table 2. Summary of radiocarbon dates associated with middle to late Quaternary deposits in the Cook Inlet trough and vicinity. Interpretations of stratigraphic context and chronological significance may differ considerably from original sources because of re-evaluation of glacial history. Footnotes provided at end of table. BCF = Bootlegger Cove Formation

Sample ^a locality	Laboratory/field number	Material and stratigraphic context	Chronological significance	Radiocarbon age (¹⁴ C yr B.P.)	Source
C1	GX-18230 [91RE65 S-2C]	Sphagnum peat from depth of 234.5-237.5 cm in peat boring; beneath tephra KL-115	Maximum age for tephra KL-115 but dates reversed	6,020 ± 175 ^b	This study (section 56)
C2	Beta-47182 [91RE3 C-1]	Organic silt with some wood and fibrous peat from beneath 1.8-m-thick surface peat and underlying 0.7-m-thick clayey estuarine silt with trace pebbles and organic material (rhizomes)	Maximum age for upper 0.7 m of estuarine silt near mouth of Kenai River	6,120 ± 50 ^b	This study (section 30A)
C3	Beta-45211 [91-16 & 16B]	Basal sample of 2-m-thick surface peat overlying clayey estuarine silt on tread of 6-m terrace	Maximum age for surface peat on 6-m terrace near mouth of Kenai River	6,190 ± 80 ^b	Combellick and Reger (1994, locality 91-16) (section 30B)
C4	GX-18232 [92RE4 S-5]	Fibrous sphagnum peat and organic silt from depth of 101.5-103.5 cm in peat boring; 1.5 cm above tephra KL-123	Minimum age for tephra KL-123	6,360 ± 145 ^b	This study (section 18)
C5	GX-18225 ^c [92RE4 S-8]	Fibrous sphagnum peat and organic silt from depth of 105.5-113 cm in peat boring; beneath tephra KL-123	Maximum age for tephra KL-123	6,801 ± 55 ^b	This study (section 18)
C6	Beta-49103 [KE1]	Top of 0.2-m-thick peat from depth of 4.2 m at base of 2-m-thick clayey estuarine silt	Maximum age for upper 2 m of estuarine fill near mouth of Kenai River	7,170 ± 120 ^b	Combellick and Reger (1994, borehole KE1) (section 30C)
C7	GX-16520 [90RE72 C-1]	Peat overlying 12.4 m of nearshore sand and gravel above dropstone diamicton of lower marine terrace	Minimum age for emergence of nearshore granular sediments in Kalifornsky beach area	7,175 ± 115 ^b	This study (section 45)

Table 2. (continued)

Sample ^a locality	Laboratory/field number	Material and stratigraphic context	Chronological significance	Radiocarbon age (¹⁴ C yr B.P.)	Source
C8	GX-16519 [90RE39 C-5]	Organic silt beneath 1.4-m-thick section of eolian and paludal silts, tephra, and peat and above 53-cm-thick fluvial rhythmite in fill of channel cut into Moosehorn-age terminal moraine	Minimum age for recession of Moosehorn-age glacier from Coho area	7,560 ± 340 ^b	This study (section 60)
C9	GX-18229 [91RE65 S-2A]	Sphagnum peat from depth of 229-232.5 cm in peat boring; above tephra KL-115	Minimum age for tephra KL-115	7,605 ± 210 ^b	This study (section 56)
C10	GX-18227 [91RE64A S-3A]	Sphagnum peat from depth of 293-296 cm in peat boring; above tephra KL-113	Minimum age for tephra KL-113	7,725 ± 210 ^b	This study (section 25)
C11	Beta-49111 [KS1]	Top of 1.1-m-thick peat at depth of 6.3 m beneath 4.5 m of estuarine clayey silt fill in lower Kaslof River valley	Maximum age for flooding of lower Kaslof River valley by estuarine waters	7,740 ± 60 ^b	Combellick and Reger (1994, borehole KS1) (section 50)
C12	GX-16517 [90MW104]	Organic silt from depth of 55 cm at base of kettle fill in moraine of Moosehorn age	Minimum age for recession of Moosehorn-age glacier from Sterling area	7,835 ± 240 ^b	This study (section 33)
C13	W-2151	Peat in lower part of 1.2-m-thick sand underlain by 1.2 m of gravel and 12.7 m of interbedded sand and glacioestuarine diamicton	Minimum age for recession of Skilak-age glacier from Potter area (Potter Hill railroad cut)	7,890 ± 250	Sullivan and others (1970, p. 332)
C14	Beta-49104 [KE1]	Base of 0.2-m-thick peat from depth of 4.4 m beneath 2 m of clayey estuarine silt and above sand and gravel	Minimum age for gravel below depth of 4.4 m in 6-m terrace near mouth of Kenai River	8,080 ± 250 ^b	Combellick and Reger (1994, borehole KE1) (section 30C)
C15	---	Wood fragments from laminated silt near depth of 93 m in estuarine deposits	Minimum age for recession of Elmendorf-age glacier from Portage area	8,230 ± 100	Bartsch-Winkler and others (1983), Bartsch-Winkler and Schmolt (1984)
C16	W-2306	Basal peat overlying glaciodeltaic deposits	Minimum age for recession of Skilak-age glacier from Fire Island	8,290 ± 250	Schmolt and others (1981, locality 3)

Table 2. (continued)

Sample ^a locality	Laboratory/field number	Material and stratigraphic context	Chronological significance	Radiocarbon age (¹⁴ C yr B.P.)	Source
C17	GX-18228 [91RE64A S-3C]	Sphagnum peat from depth of 297.5–300 cm in peat boring; beneath tephra KL-113	Maximum age for tephra KL-113	8,375 ± 210 ^b	This study (section 25)
C18	BGS-1279	Transported <i>Alnus</i> branch in deltaic sand, silt, and gravel 0.8 m below upper outwash sand and gravel	Minimum age for recession of Elmendorf-age glacier from lower Kachemak Bay in Halibut Cove area	8,400 ± 100 ^b	Wiles (1992), Wiles and Calkin (1994)
C19	GX-18405 [92RE30 S-1]	Peaty organic silt from base of 2.6-m-thick peat in former drainage channel	Minimum age for fluvial activity in drainage channel northeast of Anchor Point	8,515 ± 235 ^b	Reger and Petrik (1993), this study (section 67)
C20	L-163B ^d	Wood and organic silt from near base of lower 1.2-m-thick peat unconformably overlying sequence of thinly laminated silt and clay with some sand and gravel	Minimum age for advance of Killey-age glacier from northwest Boulder Point area	8,650 ± 450	Olson and Broecker (1959, p. 6), Karlstrom (1964, pls. 4 and 6, locality E-1, table 3)
C21	GX-18404 [92RE30 F-1]	Wood from base of 2.6-m-thick peat in former drainage channel	Minimum age for fluvial activity in drainage channel northeast of Anchor Point	8,745 ± 100 ^b	Reger and Petrik (1993), this study (section 67)
C22	GX-15229 ^c	Organic silt from depth of 8.5 m in estuarine fjord filling	Minimum age for recession of Elmendorf-age glacier from upper Knik Arm	8,850 ± 120 ^b	Combellick (1990, 1991, borehole KA1)
C23	GX-14445 [88Re53 C-1]	Peaty organic silt from base of 1.5-m-thick wood-bearing paludal deposit above 20 cm of olive-gray paludal silt overlying outwash sand and gravel	Minimum age for retreat of Elmendorf-age glacier and deposition of outwash alluvium at mouth of canyon of upper Little Susitna River	9,120 ± 350 ^b	This study (section 2)
C24	GX-5019 [77JTK49 C-1]	Silty peat with scattered wood fragments from base of 0.9-m-thick layer underlying 1.2-m-thick silty alluvial-fan sand and overlying gravelly sand deposited in ice-marginal bedrock channel	Minimum age for thinning of Elmendorf-age glacier blocking mouth of Little Susitna River canyon north of Palmer	9,155 ± 215	Reger and Updike (1983a, locality C)

Table 2. (continued)

Sample ^a locality	Laboratory/field number	Material and stratigraphic context	Chronological significance	Radiocarbon age (¹⁴ C yr B.P.)	Source
C25	L-163D ^d	Organic silt underlying 9.1 m of Holocene eolian sand and silt and overlying loess capping till weathered to depths of 0.9 to 1.5 m	Minimum age for recession of Killey-age glacier from Point Possession area	9,200 ± 600	Broecker and others (1956, p. 156), Karlstrom (1964, pls. 4 and 6, locality D-2, table 3)
C26	GX-15294	Organic silt from depth of 3.8 m in estuarine deposits	Minimum age for recession of Elmendorf-age glacier from Goose Bay area	9,255 ± 420 ^b	Combellick (1990, 1991, borehole KA4B)
C27	Beta-59790 [91RE2, 91-30, & 91-30R]	Coarsely fibrous woody sedge peat from base of 2.3-m-thick surface peat on 11-m terrace	Maximum age for surface peat and minimum age for underlying sand in 11-m terrace near mouth of Kenai River	9,260 ± 100 ^b	Combellick and Reger (1994, locality 91-30, 30R) (section 23)
C28	W-536	Peat from base of 1.5-m-thick bed overlying pond deposits on top of diamicton thought to overlie and interfinger with extensive deltaic deposits that interfinger with BCF	Minimum age for recession of Skilak-age glacier from Fire Island and retreat of estuarine waters in which BCF was deposited	9,300 ± 250	Miller and Dobrovolsky (1959, p. 32), Rubin and Alexander (1960, p. 165), Karlstrom (1964, pl. 6, locality C-2, table 3)
C29	GX-10782	Peat from depth of 3.6 m in paludal deposits capping upper marine terrace between Kenai and Kaslof Rivers	Minimum age for marine deposits on upper terrace in Kaslof area	9,410 ± 225	Rawlinson (1986, core SK34)
C30	Beta-59789 [91RE2, 91-30, & 91-30R]	Wood from middle of 10-cm-thick sand underlying 2.3-m-thick surface peat on 11-m terrace	Age of sand beneath surface peat on 11-m terrace near mouth of Kenai River	9,440 ± 90 ^b	Combellick and Reger (1994, locality 91-30, 30R) (section 23)
C31	Beta-59791 [91RE2, 91-30, & 91-30R]	Peat and organic silt from just beneath sharp lower contact 10-cm-thick sand on 11-m terrace	Maximum age of sand beneath surface peat on 11-m terrace near mouth of Kenai River	9,470 ± 90 ^b	Combellick and Reger (1994, locality 91-30, 30R) (section 23)
C32	L-137C ^d	Compressed and deformed peat beneath 4.6 m of Holocene eolian sand and silt and overlying organic silt (loess) capping Killey-age diamicton	Minimum age for recession of Killey-age glacier from Point Possession area	9,500 ± 650	Broecker and others (1956, p. 156), Karlstrom (1964, pls. 4 and 6, locality D-3, table 3)

Table 2. (continued)

Sample ^a locality	Laboratory/field number	Material and stratigraphic context	Chronological significance	Radiocarbon age (¹⁴ C yr B.P.)	Source
C33	L-137L ^d	Wood from base of 3-m-thick peat overlying 6 m of channel sand and gravel resting on pre-Naptowne till	Minimum age for alluvium in former channel near Ninitchik	9,600 ± 650	Broecker and others (1956, p. 156), Karlstrom (1964, pl. 4, locality I, table 3)
C34	GX-5209 [77RE18 C-2]	Woody fibrous sedge peat from lowest 3 cm of 36-cm-thick peat overlying 10-cm-thick organic silt above 5- to 10-cm-thick flowtill overlying 140-cm-thick channel gravel cut into till of Moosehorn age	Minimum age for channel postdating Moosehorn-age advance from northwest in Coho area	9,665 ± 230	This study (section 61)
C35	W-2936	Peat from base of paludal deposit overlying postglacial alluvium	Minimum age for recession of glacier from type Elmendorf moraine in lower Knik Arm	9,760 ± 350	Yehle and others (1990, locality 3)
C36	GX-10649 (RC84-15-1C)	Peat from depth of 1.8 m in organic sediments ponded behind outer end moraine	Minimum age for readvance of glaciers in Tincan and Lyons Creek valleys after recession of late Elmendorf-age glacier from upper Turnagain Arm	9,850 ± 390	Reger and others (1995, locality AC)
C37	W-336	Twigs and wood fragments from base of 2.1-2.4-m-thick organic kettle filling in terminal moraine of Elmendorf age	Minimum age for recession of Elmendorf-age glacier from terminal moraine in Willow Creek valley	9,870 ± 250	Rubin and Alexander (1958, p. 1483)
C38	W-2302	Compressed wood and peat from beneath diamicton and estuarine silt and clay and overlying bedded deltaic gravel	Minimum age for recession of Elmendorf-age glacier from Girdwood area and deposition of BCF in upper Turnagain Arm	10,180 ± 350	Bartsch-Winkler and Schmoll (1984)
C39	Beta-33348	Aquatic plant material from base of 2-m-thick lacustrine silt-clay rhythmite	Minimum age for recession of Elmendorf-age glacier from lower Kachemak Bay in Halibut Creek area	10,240 ± 70 ^b	Wiles (1992), Wiles and Calkin (1994)

Table 2. (continued)

Sample ^a locality	Laboratory/field number	Material and stratigraphic context	Chronological significance	Radiocarbon age (¹⁴ C yr B.P.)	Source
C40	Beta-47180 [91RE1 C-1]	Sphagnum peat from base of 2-m-thick postglacial peat overlying 6.8 m of clayey gravel till of Killey age	Minimum age for retreat of Killey-age glacier in Homer area	10,310 ± 70 ^b	This study (section 74)
C41	W-474	Organic silt from near base of bog deposit buried beneath eolian sand and overlying diamicton	Minimum age for recession of Killey-age glacier from Point Possession area	10,370 ± 350	Rubin and Alexander (1958, p. 1479), Karlstrom (1964, pls. 4 and 6, locality D-1, table 3)
C42	GX-15215	Organic silt from depth of 16.8 m in estuarine deposits	Minimum age for recession of Elmendorf-age glacier from Girdwood area	10,375 ± 310	Combellick (1990, 1991, borehole TA1)
C43	GX-18231 [91RE65 S-4]	Sphagnum peat from depth of 305-310 cm in peat boring; base of thawed kettle fill over permafrost	Minimum age for base of kettle fill in Moosehorn-age moraine in Kasilof area	10,380 ± 285 ^b	This study (section 56)
C44	Beta-49112 [KS1]	Base of 1.1-m-thick peat at depth of 7.4 m beneath 4.5 m of estuarine clayey silt and above at least 0.5 m of silt and fine sand with numerous pebbles	Minimum age for incision of lower valley of Kasilof River	10,450 ± 110 ^b	Combellick and Reger (1994, borehole KS1) (section 50)
C45	GX-6041 [78RE34-4]	Organic silt 0.1 to 0.2 m below top of 1-m-thick silty and sandy peat underlying 0.6-m-thick woody sphagnum peat and overlying 0.4-m-thick organic silt on top of sandy gravel at base of scarp cut into pitted outwash of Elmendorf age	Minimum age for outwash from Elmendorf-age moraine to east and cutting of scarp in the Red Shirt Lake area by estuarine waters in which BCF was deposited	10,720 ± 460	Reger and Updike (1983a, locality 1)
C46	GX-15224	Organic silt from depth of 15.4 m in estuarine deposits	Minimum age for recession of Elmendorf-age glacier from Portage area	10,730 ± 525	Combellick (1990, 1991, borehole TA8)
C47	GX-18234 [92RE21 S-1]	Organic silt from base of 7.7-m-thick peat with scattered wood overlying glacier-deformed diamicton of Killey age	Minimum age for recession of Killey-age glacier from Point Possession area	10,895 ± 120 ^b	Combellick and Reger (1994), this study (section 6)

Table 2. (continued)

Sample ^a locality	Laboratory/field number	Material and stratigraphic context	Chronological significance	Radiocarbon age (¹⁴ C yr B.P.)	Source
C48	Beta-47181 [91RE2 C-1]	Interbedded organic silt and inorganic fine sand and silt beneath 2.3 m of surface peat and 0.3 m of fluvial sand on 11-m terrace of lower Kenai River	Minimum age for 11-m terrace of lower Kenai River	11,280 ± 150 ^b	Combellick and Reger (1994, locality 91-30, 30R) (section 23)
C49	GX-15241	Organic silt from depth of 7.7 m in estuarine deposits	Minimum age for recession of Elmendorf-age glacier from upper Knik Arm	11,400 ± 720 ^c	Combellick (1990, 1991, borehole KA6)
C50	Beta-5581 [82RE40 C-1]	Peat from base of 1.8-m-thick bed overlying BCF	Minimum age for recession of Skilak-age glacier from Fire Island and emergence from estuarine waters in which BCF was deposited	11,450 ± 150	Reger and Updike (1983a, p. 202)
C51	GX-10785 [81RE106 C-4]	Organic fine silty sand from base of 0.3-m-thick paludal organic fine sand and silt underlying 4.5-m-thick surface peat and overlying channelled outwash gravel of Skilak age ^f	Minimum age for Skilak-age outwash in Little Willow Creek area	11,540 ± 450	This study (section 1)
C52	W-540	Peat from base of 2.4-m-thick bed overlying 3 m of sand that overlies 1.8 to 3 m of BCF	Minimum age for emergence from glacioestuarine waters in which BCF was deposited in Point Woronzof area	11,600 ± 300	Rubin and Alexander (1960, p. 165), Miller and Dobrovolny (1959, p. 68, pl. 9), Schmoll and others (1972, locality E)
C53	W-2375	Peat from beneath colluvium overlying till of type Elmendorf moraine	Minimum age for Elmendorf advance in lower Knik Arm	11,690 ± 300	Schmoll and others (1972, locality F), Spiker and others (1977, p. 346)
C54	GX-16521 [90RE102 C-1]	Compressed wood from depth of 70 cm in 94-cm-thick unit of interbedded thin peat, organic silt, pond clay, and tephra filling kettle in Killey-age terminal moraine	Minimum age for recession of Killey-age glacier from Point Possession area	11,905 ± 180 ^b	This study (section 7)

Table 2. (continued)

Sample ^a locality	Laboratory/field number	Material and stratigraphic context	Chronological significance	Radiocarbon age (¹⁴ C yr B.P.)	Source
C55	W-360	Basal organic pond silt in depression on Skilak-age moraine	Minimum age for recession of Skilak-age glacier in Deception Creek area ^g	11,930 ± 250	Rubin and Alexander (1958, p. 1483), Karlstrom (1964, pl. 1, locality T, table 3)
C56	Beta-11174	Basal peaty silt in pond sediments and peat filling depression on late Naptowne moraine	Minimum age for recession of Matanuska Glacier	12,210 ± 120	Williams (1986)
C57	Beta-5580 [82RE20 C-1]	Organic silt from beneath 1.8-m-thick peat overlying 3-m-thick fan-delta sand above BCF	Minimum age for recession of Skilak-age glacier from Point MacKenzie and retreat of estuarine waters in which BCF was deposited	12,250 ± 140	Reger and Updike (1983a, p. 202), this study (section 78)
C58	W-2589	Basal organic swamp deposit overlying till of type Elmendorf moraine	Minimum age for recession of glacier from type Elmendorf moraine in lower Knik Arm	12,350 ± 350	Yehle and others (1990, 1991, locality 4)
C59	W-5518	Pebbly organic silt from depth of 4.38 to 4.57 m in Circle Lake core	Minimum age for recession of Moosehorn-age glacier from upper Kachemak Bay	12,800 ± 300	Ager and Shaw (1986), Ager (written commun., 1992)
C60	GX-16522 [90RE102 C-2]	Organic clayey silt from depth of 80 cm in 94-cm-thick unit of interbedded thin peat, organic silt, pond clay, and tephra filling kettle in Killey-age terminal moraine	Minimum age for recession of Killey-age glacier from Point Possession area	12,860 ± 195 ^b	This study (section 7)
C61	W-416	Peat from base of 0.9- to 1.5-m-thick section of lacustrine organic clay, silt, and sand overlying deformed glaciofluvial gravel and sand graded to Killey-age ice limit at East Foreland	Minimum age for deposition of Killey-age outwash and melting of underlying stagnant glacial ice of Killey age in Nikiski area ^h	12,900 ± 300	Rubin and Alexander (1958, p. 1479), Karlstrom (1964, pls. 4 and 6, locality F-2, table 3)
C62	USGS-2175	Basal peaty silt in pond sediments and peat filling depression on late Naptowne moraine	Minimum age for recession of Matanuska Glacier	13,100 ± 60	Williams (1986)
C63	AA-2227 ^c [82RE14]	<i>Mya truncata</i> shells from silty-clay facies of BCF 1 m above contact with ice-stagnation deposits of Skilak stage	Dates BCF at mouth of Knik Arm	13,470 ± 120	Reger and others (1995, locality N), this study (section 77)

Table 2. (continued)

Sample ^a locality	Laboratory/field number	Material and stratigraphic context	Chronological significance	Radiocarbon age (¹⁴ C yr B.P.)	Source
C64	W-748	Silty peat with twigs from base of organic lake sediments overlying deformed outwash gravel graded to Killey-age ice limit at East Foreland	Minimum age for deposition of Killey-age outwash and melting of underlying stagnant glacial ice of Killey age in Nikiski area ^b	13,500 ± 400	Rubin and Alexander (1958, p. 1479), Karlstrom (1964, pls. 4 and 6, locality G-1, table 3)
C65	W-2151	Mollusk shells from macrofossil-rich zone of BCF	Dates middle or upper sublittoral glacioestuarine environment in which BCF was deposited in Point Woronzof area	13,690 ± 400	Sullivan and others (1970, p. 333), Schmoll and others (1972, locality A)
C66	GX-20129 ^c [82Re36]	<i>Macoma balthica</i> shells from 3-m-thick dropstone-rich, thin-bedded sand in upper BCF overlain by 3 m of colluvium	Dates upper BCF west of Hope just beyond Elmendorf maximum in Turnagain Arm	13,718 ± 160 ^b	Reger and others (1995, locality U), this study (section 75)
C67	W-4827	Organic mud from depth of 250–260 cm beneath bottom of Hidden Lake	Minimum age for retreat of Skilak-age glacier from Hidden Lake basin	13,730 ± 110	Rymer and Sims (1982, core HL-4-M), Sims (written commun., 1992)
C68	W-2389 [82Re11]	Mollusk shells from macrofossil-rich zone of BCF	Dates middle or upper sublittoral glacioestuarine environment in which BCF was deposited in lower Knik Arm	13,750 ± 500	Schmoll and others (1972, locality D), Spiker and others (1977, p. 346)
C69	W-2919	Mollusk shells of BCF incorporated into till of Elmendorf-age advance ¹	Dates BCF and maximum age for Elmendorf-age advance in upper Turnagain Arm	13,900 ± 400	Schmoll and Yehle (1983, locality A; 1986, locality B4), Bartsch-Winkler and Schmoll (1984)
C70	GX-20127 ^c [82Re17]	<i>Mya truncata</i> shells from interbedded medium sand and silt layers up to 20 cm thick 6 m below top of BCF	Dates upper BCF west of Point MacKenzie	13,994 ± 90 ^b	Reger and others (1995, locality P), this study (section 76)
C71	GX-20128 [82Re20]	<i>Mya truncata</i> shells from dropstone-rich diamicton 3 m below top of BCF	Dates BCF west of Point MacKenzie	14,078 ± 214	Reger and others (1995, locality M), this study (section 78)

Table 2. (continued)

Sample ^a locality	Laboratory/field number	Material and stratigraphic context	Chronological significance	Radiocarbon age (¹⁴ C yr B.P.)	Source
C72	GX-19989 ^c [82Re12]	<i>Balanus</i> plates from 1- to 2-cm-thick sand layers interbedded with clayey silt in upper BCF overlain by up to 5 m of fan-delta sand	Dates upper BCF at Point MacKenzie	14,100 ± 90 ^b	Reger and others (1995, locality K), this study (section 5)
C73	GX-16529 ^c [82RE6]	<i>Hiatella arctica</i> and <i>Macoma balthica</i> shells from colluvium derived from BCF ¹	Dates BCF and nearby Elmendorf-equivalent advance in Hope area	14,160 ± 140 ^b	Reger and others (1995, locality V)
C74	GX-17133 ^c [82RE5]	<i>Hiatella arctica</i> shells from colluvium derived from BCF	Dates BCF and nearby Elmendorf-equivalent advance in Hope area	14,200 ± 100 ^b	Reger and others (1995, locality W)
C75	GX-16524 ^c [82RE4]	<i>Macoma balthica</i> shells from BCF incorporated into till of Elmendorf-age advance ¹	Dates BCF and maximum age for Elmendorf-age advance in upper Turnagain Arm	14,290 ± 140 ^b	Reger and others (1995, locality X), Schmoll and Yehle (1986, locality B4)
C76	AA-2226 ^c [77RE22F]	<i>Hiatella arctica</i> shells from 6 m below top of BCF and 0.3 m above Skilak-age diamicton	Dates BCF in lower Knik Arm and minimum age for recession of Skilak-age glacier from lower Knik Arm	14,300 ± 140	Reger and others (1995, locality J), this study (section 4)
C77	W-2367	Mollusk shells from macrofossil-rich zone of BCF	Dates middle or upper sublittoral glacioestuarine environment in which BCF was deposited in Point MacKenzie area	14,300 ± 350	Schmoll and others (1972, locality C), Spiker and others (1977, p. 346)
C78	W-4292	Shells in glacioestuarine silt and clay of BCF	Dates BCF in lower Beluga River area	14,350 ± 200	Schmoll and Yehle (1983, locality B; 1986, locality B5), Schmoll and others (1984, locality B5)
C79	W-2369	Mollusk shells from macrofossil-rich zone of BCF	Dates middle or upper sublittoral glacioestuarine environment in which BCF was deposited in Point Woronzof area	14,900 ± 350	Schmoll and others (1972, locality B), Spiker and others (1977, p. 346)

Table 2. (continued)

Sample ^a locality	Laboratory/field number	Material and stratigraphic context	Chronological significance	Radiocarbon age (¹⁴ C yr B.P.)	Source
C80	GX-16528 ^c [90RE72 C-2]	Calcareous <i>Balanus</i> plates from 0.6 m below top of platy, dense, pebbly dropstone diamicton of BCF	Dates BCF in upper marine terrace along Kalifornsky beach	16,000 ± 150 ^b	This study (section 45)
C81	GX-16527 ^c [90RE72 C-1]	Calcareous <i>Balanus</i> plates from 0.5 m above base of 3-m-thick, massive dropstone diamicton of BCF	Dates BCF in upper marine terrace along Kalifornsky beach	16,090 ± 160 ^b	This study (section 45)
C82	W-4937	Calcareous <i>Balanus</i> plates in glaciomarine silt and clay assigned to BCF	Dates BCF in upper marine terrace along Kalifornsky beach	16,340 ± 140	Schmoll and Yehle (1983; 1986, locality B7), Schmoll and others (1984, locality B7)
C83	WSU-4304 [91RE39 F-1]	Calcareous <i>Balanus</i> plates from 1 m below top of deformed glaciomarine fine sand and silt assigned to BCF	Dates BCF and close maximum age for fluctuating tidewater glacier in vicinity of Kenai	16,480 ± 170 ^b	This study (section 20)
C84	GX-18233 [92RE18 S-1]	Organic silt at base of 10-cm-thick sand layer in upper fan-delta gravel of Killey age in Kasilof area	Probably contaminated by finely divided clastic Tertiary coal	26,240 ± 2,100 ^b	This study (section 59)
C85	L-163A ^d	Residual after removal of humic acid from iron-oxide-stained lignitized log in silt, sand, and gravel of Killey-age outwash graded to ice limit at East Forceland	Probably reworked material without significance for dating enclosing sediments in Nikiski area ¹	39,000 ± 2,600 ^k (39,000 ± 2,000 for humic-acid fraction)	Olson and Broecker (1959, p. 5-6), Karlstrom (1964, pls. 4 and 6, locality 5, table 3)
C86	L-137D ^d	Lignitized log from base of 15-m-thick iron-oxide-stained and flexured gravel overlying glaciolacustrine or glacioestuarine deposits	Probably reworked material without significance for dating enclosing sediments in Kenai area	>24,000	Broecker and others (1956, p. 156), Karlstrom (1964, pls. 4 and 6, locality 7, table 3)
C87	L-117M ^d	Log from basal outwash of Killey age	Probably reworked material without significance for dating enclosing sediments in Boulder Point area	>25,000	Broecker and others (1956, p. 156), Karlstrom (1964, pls. 4 and 6, locality 3, table 3)
C88	W-76	Partly lignitized wood from outwash sand	Probably reworked material without significance for dating enclosing sediments in Tustumena Lake area	>32,000 ¹	Suess (1954, p. 471), Karlstrom (1964, pl. 4, locality 8, table 3)

Table 2. (continued)

Sample ^a locality	Laboratory/field number	Material and stratigraphic context	Chronological significance	Radiocarbon age (¹⁴ C yr B.P.)	Source
C89	W-77	Wood from Goose Bay peat beneath till of type Elmendorf moraine	Maximum age for Elmendorf stage and minimum age for former interglaciation in Goose Bay area	>32,000 ^m	Suess (1954, p. 471), Karlstrom (1964, pls. 1 and 6, locality 1, table 3) (section 3)
C90	GX-5208 [77RE18 C-1]	Abraded, lignitized wood in friable fan-delta sand beneath drift of Moosehorn-age advance	Probably reworked material without significance for dating enclosing sediments in Coho area	>37,000	This study (section 61)
C91	W-2913	Organic clayey pond silt with occasional freshwater gastropods overlain by drift of Elmendorf advance and underlain by drift of pre-Naptowne age	Maximum age for type Elmendorf advance and minimum age for former interglaciation in Eagle River area	>37,000	Yehle and Schmoll (1989, locality 2)
C92	W-294	Woody material near base of 0.6- to 0.9-m-thick contorted organic silt overlain by 3.9 m of unsorted lacustrine organic silt and peat and underlain by 0.3- to 0.6-m-thick contorted sand and silt resting on contorted gravel	Possibly reworked material without significance for dating enclosing sediments in Kenai area ⁿ	>37,000	Rubin and Suess (1956, p. 444), Karlstrom (1964, pls. 4 and 6, locality 6, table 3)
C93	W-174	Wood from upper 15 cm of Goose Bay peat at type locality	Maximum age for type Elmendorf advance and minimum age for former interglaciation in Goose Bay area	>38,000	Rubin and Suess (1956, p. 486), Karlstrom (1964, pls. 1 and 6, locality 1, table 3) (section 3)
C94	W-1806	Woody fragments in silt overlain by gravel presumably of Elmendorf age	Maximum age for overlying Elmendorf outwash and minimum age for former interglaciation in Eagle River area	>38,000	Marsters and others (1969, p. 221), Yehle and Schmoll (1989, locality 3)
C95	W-535	Very thin peat beneath Elmendorf-age till and outwash	Maximum age for Elmendorf advance and minimum age for former interglaciation in Eagle River area	>38,000 ⁿ	Rubin and Alexander (1960, p. 164-165), Miller and Dobrovolsky (1959, p. 16, pl. 9)

Table 2. (continued)

Sample ^a locality	Laboratory/field number	Material and stratigraphic context	Chronological significance	Radiocarbon age (¹⁴ C yr B.P.)	Source
C96	W-644	Wood from base of advance outwash of type Elmendorf advance overlying compressed Goose Bay peat that overlies pre-Naptowne glacial deposits	Probably reworked material without significance for dating enclosing sediments in Goose Bay area	>40,000	Rubin and Alexander (1960, p. 169), Karlstrom (1964, pls. 1 and 6, locality 1, table 3) (section 3)
C97	W-2366	Organic fragments in 5-cm-thick brown sand beneath BCF	Maximum age for BCF in Point MacKenzie area	>40,000	Spiker and others (1977, p. 346)
C98	I-11,949 [78RE24 C-1]	Wood from upper 10 cm of 0.9- to 1.8-m-thick highly compressed Goose Bay peat that overlies 3 m of outwash gravel of pre-Naptowne glaciation and underlies 4.6 to 8.5 m of advance outwash sand that in turn underlies 6.1 to 7.6 m of till of type Elmendorf moraine	Maximum age for type Elmendorf advance and minimum age for former interglaciation in Goose Bay area	>40,000	Reger and Updike (1983a, locality R), this study (section 3)
C99	I-11,950 [78RE24 C-2]	Compressed peat from middle of 0.9- to 1.8-m-thick bed overlying 3 m of outwash gravel of pre-Naptowne glaciation and underlying 4.6 to 8.5 m of advance outwash sand and gravel that in turn underlie 6.1 to 7.6 m of till of type Elmendorf moraine	Maximum age for type Elmendorf advance and minimum age for former interglaciation in Goose Bay area	>40,000	Reger and Updike (1983a, locality R), this study (section 3)
C100	I-12,029	Wood fragments from peaty zone at base of upper glacioestuarine diamicton of Skilak-age advance	Maximum age for Skilak age advance in Potter area	>40,000 ^g	Schmoll and Yehle (1983, p. 77), Bartsch-Winkler and Schmoll (1984, p. 8)
C101	L-117L ^d	Abraded, lignitized log from lowest 0.3 m of Holocene lacustrine organic silt unconformably overlying stratified sand and gravel graded to Killey-age ice limit at East Foreland	Probably reworked material without significance for dating enclosing sediments in Nikiski area	>44,000 ^f	Olson and Broecker (1959, p. 5), Karlstrom (1964, pls. 4 and 6, locality 4, table 3)
C102	W-2154	Peat overlain by 2.7 m of fluvial gravel of Elmendorf advance and underlain by 0.6 m of gray silty clay till(?) of pre-Naptowne glaciation	Maximum age for type Elmendorf advance and minimum age for former interglaciation in Chugiak area	>45,000	Sullivan and others (1970, p. 328), Yehle and Schmoll (1989, locality 1)

Table 2. (continued)

Sample ^a locality	Laboratory/field number	Material and stratigraphic context	Chronological significance	Radiocarbon age (¹⁴ C yr B.P.)	Source
C103	W-2911	Piece of wood from gravel beneath 5 m of BCF overlain by 30 m of advance outwash gravel and till of type Elmendorf moraine	Probably reworked material without significance for dating enclosing sediments in Eagle Bay area	>45,000	Yehle and others (1990, locality 2)
C104	QL-1736 [88RE 54 S-2]	16-cm-thick organic silt from middle of 1-m-thick Goose Bay peat overlain by 6 m of advance outwash gravel and 6 m of till of type Elmendorf moraine	Minimum age for Goose Bay peat and maximum age for type Elmendorf advance in Goose Bay area	>73,400 ^b	This study (section 3)

^aTo locate sample sites and nearby geographic features, see table 1 and sheets 1–5.

^bSample corrected for natural isotopic fractionation based on ¹³C content.

^cAtomic mass spectrometer (AMS) date.

^dKarlstrom (1964, p. 59) accepted as generally valid all solid-carbon dates from Lamont Observatory younger than 14,000 yr B.P. because they are consistent with results obtained by the gas-proportional technique during reruns of the same samples. Reruns of samples initially dated between 14,000 and 22,000 yr B.P. by the black-carbon method produced infinite dates by the gas-counting method (Olson and Broecker, 1959, p. 5).

^eBecause disseminated organic material, which could include very fine grained detrital coal, was dated, this age could be spuriously old (Reger and others, 1995, locality C).

^fDated sample from near bottom of section G–G' at station 21 (Cameron and others, 1981, sheet 1).

^gThese moraines were attributed to the Eklutna glaciation by Karlstrom (1964, pl. 1) and to the Knik glaciation by Reger and Updike (1983a, pl. 1).

^hKarlstrom (1964, p. 24) interpreted deformation in this and other sections in the East Foreland-Lower Salamatof Lake area to be the result of glaciotectionic stresses generated during repeated eastward advances by the Trading Bay lobe. We interpret the deformation there to be the result of both glaciotectionic stresses generated by grounding of partially floating tidewater glaciers and the melting of stagnant glacial ice on which outwash alluvium was deposited.

ⁱSchmoll and Yehle (1986, p. 205) interpreted sediments enclosing 13,900-yr-old mollusk shells in the roadcut near Mile 99 of Seward Highway to be colluvial bedrock rubble incorporating reworked sediments of the Bootlegger Cove Formation and, based on an extrapolated age of 14,000 yr for basal sediments in a 93-m core at Portage (Bartsch-Winkler and others, 1983), concluded that Turnagain Arm was ice free about 14,000 yr ago. We interpret the exposure to be BCF deposits overridden by a rapid westward advance of the Elmendorf-age glacier into estuarine waters of upper Turnagain Arm. We believe that crushed shells in the exposure, were preserved in till in a leeward pressure shadow provided by the bedrock outcrop along the east side of the exposure, perhaps because the overriding glacier was at least partially floating.

^jKarlstrom (1964, p. 24, table 3) interpreted sample W-163A, a transported log, as dating an early Naptowne (Pro-Naptowne) advance from the west side of Cook Inlet.

^kGas-counting rerun of sample 163A, which was initially dated at 22,000 ± 2,000 yr B.P. by the black-carbon method (Olson and Broecker, 1959, p. 6). More recently, this sample was redated older than the maximum limit of radiocarbon dating (Meyer Rubin, in Schmoll and others, 1984, p. 27).

^lAcetylene rerun of sample L-117J, which was previously dated by the solid-carbon technique at 15,800 ± 400 yr B.P. (Kulp and others, 1951, p. 568).

^mAcetylene rerun of sample L-117A, which was previously dated by the solid-carbon method at 19,000 ± 900 yr B.P. (Kulp and others, 1952, p. 412–413).

ⁿKarlstrom (in Rubin and Suess, 1956, p. 444) attributed the "highly weathered and contorted" gravel at the base of this section to the Eklutna glaciation and deformation of the overlying contorted silt to the maximum advance of the Knik or Naptowne glaciation, probably the latter.

^oReanalysis of sample L-101B, which was initially dated by the solid-carbon method at 14,300 ± 600 yr B.P. (Kulp and others, 1951, p. 568).

^pOriginally dated at 34,000 ± 2,000 yr B.P. (W-1804) by the solid-carbon method (Marsters and others, 1969, p. 220).

^qOriginally dated at 19,200 ± 1,000 yr B.P. (L-117L) by the solid-carbon method (Kulp and others, 1952, p. 412).

^rSample enriched 9.41 times by Minze Stuiver at University of Washington Quaternary Isotope Laboratory.

Figure 1. Distribution of 104 radiocarbon dates older than 6,000 ^{14}C yr B.P. in the Cook Inlet region. Symbols indicate materials analyzed: b = Balanus plate, ha = humic-acid extract, l = lignite or lignitized wood, m = mollusk shell, o = organic silt or sand, p = peat, w = wood or wood fragments.

The major-oxide geochemistry of the purified glass shards was analyzed with the Kevex Series 82 Electron Microprobe in the Department of Geology, Washington State University, using an 8- μ m-wide electron beam operated at 15 kV and 11.5 nA. This instrument was calibrated at least once daily, using standards CCNM-11 (obsidian), K-411 (National Bureau of Standards glass), and CV-A99 (basaltic glass) to ensure precise and accurate results. Individual glass shards were exposed to the electron beam for 10 seconds, and the resulting data were normalized to 100 percent (table 3). Glass concentrates and grain mounts are archived in the Alaska Tephrochronology Center (ATC) at the University of Alaska (Fairbanks).

GEOCHEMICAL RESULTS

Among the 88 tephra samples analyzed, single tephtras are represented by 63 samples (71.6 percent) and mixed tephtras, which possibly include shards of up to four distinct chemical populations, are represented by 12 samples (13.6 percent). Although 13 samples (14.8 percent) were collected from volcanic-ash layers that appear to be composed of one tephtra in the field, their shard geochemistry is so variable that we could not isolate a meaningful population, and the results are not reported, except to show their stratigraphic positions (app. A). These samples are indicated by an asterisk after the sample number in table 1 and appendix A. In this study we recognize 16 chemically distinct tephtras (table 3).

CORRELATION, DISTRIBUTION, AND AGE

Mean major-oxide compositions of shards in tephtra samples from Kenai Lowland and vicinity (table 3) were compared to microprobe geochemistry of tephtras from Hayes volcano (Riehle, 1985; Begét, Reger, and others, 1991; Campbell, unpub. data), Mt. Spurr (Riehle, 1985), Mt. Redoubt (Riehle, 1985), Mt. Iliamna (Riehle, 1985), Mt. Augustine (Riehle, 1985; Begét, unpub. data), cores from Skilak Lake (Stihler, 1991; Begét and others, 1994), Aniakchak caldera (Riehle and others, 1987), Kaguyak caldera (Swanson, unpub. data), the 1912 eruption of Mt. Katmai (Avery, unpub. data), the upper drainage of Susitna River (Dilley, 1988, unpub. data; ATC, unpub. data), and interior Alaska (Westgate and others, 1983, 1990; Westgate, 1988; Begét and Keskinen, 1991; Begét, Reger, and others, 1991).

In this study, correlations of tephtras at different field localities are primarily based on geochemical similarities as determined by electron microprobe and most are considered tentative. The exceptions are (a) the Lethe tephtra, which has a distinctive shard morphology and geochemistry and a consistent mineralogy, and (b) the Stampede tephtra, for which we developed mineralogical data and

stratigraphic information. A similarity coefficient (SC) (Borchardt and others, 1972) of 0.96 or greater indicates that a tephtra pair is either part of the same tephtrafall or that they are members of a tephtra set with a high degree of similarity (Riehle, 1985). Values of 0.94 or 0.95 indicate that the pair of tephtras was deposited during the same tephtrafall—in which concentrations of one or more elements are variable—or that they are members of the same tephtra set (where supported by stratigraphic or mineralogic evidence). Values of 0.90 to 0.93 indicate that the samples are members of the same tephtra set but not the same tephtrafall.

LATE QUATERNARY TEPHTRAS

LETHE TEPHTRA

(MEAN $\text{SiO}_2 = 72.78 \pm 0.27$ PERCENT)

The most widespread tephtra we document in Kenai Lowland is the Lethe tephtra. This light yellowish-brown to orange volcanic-ash layer is identified at 29 localities in a narrow band from just south of Anchor River northeastward to just north of Swanson River (table 3, fig. 2). Correlation within this set of samples is good to excellent ($\text{SC} = 0.93\text{--}0.99$) (table 4), and they undoubtedly almost all represent the same tephtrafall. The geochemistry of Lethe shards is very consistent as indicated by the small standard deviations in all eight major-oxide contents (table 3). The single exception could be sample KL-050p1, which has lower similarity coefficients than the other 30 samples.

The distinctive yellowish-brown to orange color is due to variable thicknesses of iron oxides that formed on shard surfaces during weathering of this relatively iron-rich dacitic tephtra. Unweathered glass is light gray in transmitted light. Lethe shards are robust compared to other tephtras in the area, tend to be platy or blocky, and contain few to numerous vesicles that are commonly stretched. Triple junctions and bubble walls are commonly preserved. Petrographic studies by Pinney (1993) demonstrate that populations of iron-magnesian minerals are dominated by orthopyroxene and clinopyroxene in the Lethe tephtra. The former is generally three to four times more plentiful than the latter. Amphibole (green) content is low—generally 0 to 5 percent.

In samples from five sections, shards of Lethe tephtra are mixed with shards of other tephtras (table 3). This mixing could result from simultaneous or near-simultaneous initial deposition of these tephtras or from reworking of previously deposited tephtras. Lethe tephtra is clearly reworked in sections 13 and 66. In section 13 (fig. A13), a population of reworked Lethe shards (KL-018p1) is mixed with shards of Funny River tephtra (KL-018p2) in a layer that is stratigraphically above a layer of unmixed Lethe tephtra (KL-017). In section 66 (fig. A71), a population of redeposited Lethe shards (KL-086p3) (*Text cont'd. p. 36*)

Table 3. Average glass compositions of middle and late Quaternary tephra samples collected at 58 localities in Kenai Lowland and vicinity. Major oxides in glass separates given in normalized weight percent. One standard deviation in weight percent given below each oxide concentration. Discrete shard populations within multimodal samples indicated by letter "p" followed by population number. Number of analyses per sample = n. Sample localities shown in table 1 and sheets 1-3. Stratigraphic sections provided in appendix A

is mixed with shards of apparently reworked tephra 5 (KL-086p2) and shards of Crooked Creek tephra (KL-086p1) in a layer that is stratigraphically above a layer of unmixed Lethe tephra (KL-085). The degree of reworking is less obvious in sections 26, 41, and 52, where populations of Lethe shards are mixed with shard populations of tephra 5 and 13. Section 26 (fig. A26) was measured at Sterling on the second highest terrace of the Kenai River system. On the adjacent, highest terrace, Lethe tephra (KL-063) is unmixed in nearby section 27 (fig. A27). Because of these relations, we conclude that primary airfall Lethe tephra is redeposited in section 26 and, in the process, became mixed with tephra 13. Section 41 (fig. A45) was measured on the distal surface of the fan delta that was built by Kenai River onto the upper marine terrace between Kenai and Kasilof. Section 52 (fig. A57) was measured on the distal surface of the fan delta simultaneously built by Kasilof River onto the same marine terrace. There is a high likelihood that distal parts of both fan deltas were submerged later than medial and proximal surfaces on which we found unmixed Lethe tephra—for example, KL-124 in section 17 (fig. A17) on the fan delta at Kenai and KL-127 in section 54 (fig. A59) on the equivalent fan delta at Kasilof. Thus, reworking and mixing of Lethe and tephra 5 and 13 probably occurred at localities KEN-96 and KEN-117 (sheet 2). These arguments also lead us to tentatively conclude that deposition of tephra 5 and 13 probably slightly postdates deposition of Lethe tephra (fig. 3).

Lethe tephra is the distal airfall equivalent of the complex pyroclastic products of an explosive eruption of one of the volcanoes in the vicinity of Mt. Katmai about 260 km southwest of the southern Kenai Lowland (Pinney and Begét, 1991a,b; Pinney, 1993). On the basis of shard morphology, ferromagnesian mineral content, and microprobe geochemistry of glass shards, our Kenai Lowland samples strongly correlate with samples of Lethe tephra from the Windy Creek area (Pinney 1993) ($SC = 0.96-0.99$). Pinney and Begét (1991a,b) and Pinney (1993) provide a minimum age of $12,640 \pm 100$ ^{14}C yr B.P. (Beta-33666) for Lethe volcanoclastics in the Windy Creek area, where they overlie drift of the Iliuk stade and underlie drift of the Ukak stade of the late-Wisconsin Brooks Lake glaciation. Primary airfall Lethe tephra discontinuously covers deposits of Moosehorn and Killey stades of the Naptowne glaciation in Kenai Lowland and is not present on deposits of the Skilak stade (Reger and Pinney, 1996). Stratigraphic evidence indicates that Lethe tephra was deposited across Kenai Lowland late in the Killey stade. Killey-age glaciomarine sediments in the upper marine terrace at Kalifornsky (sheet 2, locality KEN-103) date as young as $16,000 \pm 150$ ^{14}C yr B.P. (table 2, C80) and stratigraphically underlie fan-delta sediments that are in turn overlain by Lethe-bearing loess at Kasilof (fig. A59). Thus, the known maximum age of Lethe tephra in Kenai Lowland is $16,000$ ^{14}C yr B.P. (fig. 3).

CROOKED CREEK TEPHRA

(MEAN $SiO_2 = 77.82 \pm 0.10$ PERCENT)

One of several grayish brown-weathering Holocene tephras in Kenai Lowland that are the products of brief, small eruptions of Cook Inlet volcanoes—and not known to be widely distributed—is the Crooked Creek tephra, which is first recognized and informally named in this study. This tephra is identified in 11 stratigraphic sections (table 3) in a narrow belt from west of Tustumena Lake northeast to the vicinity of Sterling (fig. 4). Correlation within this set of samples is good to excellent ($SC = 0.93-0.99$) (table 5). We know of no correlative tephras in the region, but we speculate (from the distribution and high silica content) that Crooked Creek tephra could have been erupted from Mt. Augustine. The Crooked Creek tephra was deposited between $7,725 \pm 210$ ^{14}C yr ago and $8,375 \pm 210$ ^{14}C yr ago (fig. A25; table 2, C10 and C17). It could possibly be the distal equivalent of tephra layer G, which dates $>1,830 \pm 80$ ^{14}C yr B.P. and $<39,890$ ^{14}C yr B.P. on Augustine Island (Begét and Kienle, 1992).

FUNNY RIVER TEPHRA

(MEAN $SiO_2 = 62.09 \pm 0.06$ PERCENT)

Another of the dark-weathering Holocene tephras in Kenai Lowland is the Funny River tephra, first recognized at locality KEN-85 (table 1, sheet 2) and informally named in this study. Funny River tephra is identified at five localities that form an irregular triangle with corners at Kenai, Sterling, and Coho (fig. 5); it has a low silica content relative to other tephras in the area (table 3). Correlation within this small set of samples is outstanding ($SC = 0.97-0.99$) (table 6). We know of no tephras that correlate with Funny River tephra, which was deposited after the Crooked Creek tephra (fig. 3) and has a close maximum-limiting age of $7,560 \pm 340$ ^{14}C yr B.P. (fig. A65; table 2, C8).

TEPHRA 1A

(MEAN $SiO_2 = 77.87 \pm 0.24$ PERCENT)

One of several geochemically very similar tephras in Kenai Lowland that are tentatively attributed to explosive eruptions of Mt. Augustine is tephra 1A. This volcanic ash is documented at six locations (fig. 6). Similarity coefficients within this set of samples range from 0.93 to 0.98 (table 7). Tephra layers attributed to tephra 1A are clearly redeposited in sections 57 (fig. A62), 58 (fig. A63), and 72 (fig. A77), but the other six samples are apparently undisturbed airfall samples. The stratigraphy in section 72 demonstrates that primary tephra 1A is younger than tephra 1C. Comparisons of shard geochemistry indicate that uncontaminated samples of tephra 1A correlate with Augustine ash sample H-88-2-5 collected by Begét (unpub. data) in the Homer area ($SC = 0.95-0.97$) and with sample 87A-9A collected by Begét (unpub. data) on Augustine Island ($SC = 0.94-0.98$). In section (*Text cont'd. p. 41*)

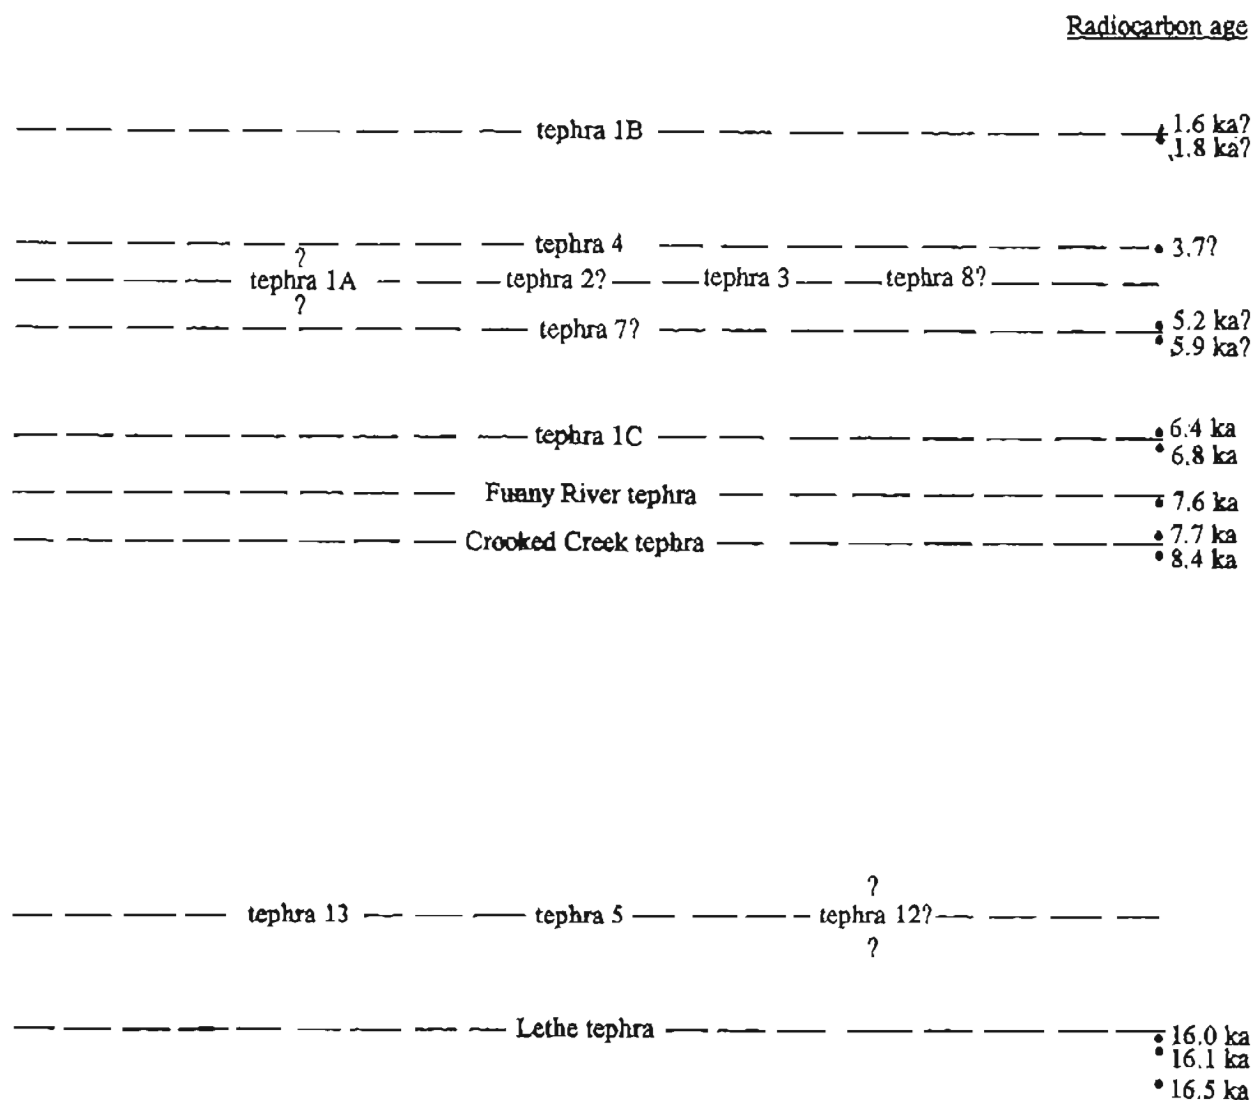

Figure 3. Tentative relative ages of late Quaternary tephras, based on stratigraphic relations in Kenai Lowland. Uncertain temporal placements are indicated by question marks above and below the pertinent tephra. Questionable tephra ages result from tentative correlations with tephras that are dated elsewhere.

39 (fig. A43) and section 59 (fig. A63), tephra 1A underlies tephra 4, indicating that tephra 1A is older (fig. 3).

TEPHRA 1B

(MEAN $\text{SiO}_2 = 77.83 \pm 0.09$ PERCENT)

Very similar to tephra 1A, tephra 1B is geochemically different enough to justify separating the two (table 3). Major-oxide contents within the set of tephra 1B samples are very consistent ($\text{SC} = 0.96\text{--}0.98$) (table 8A). Apparently undisturbed samples of tephra 1B are identified in five of six sections in the Kasilof-Kenai-Sterling area (table 3, fig. 7). Shards of tephra 1B (KL-044p1) are mixed with shards of tephra 1C (KL-044p2) in section 53 (fig. A58).

Stratigraphic superposition in section 35 (fig. A39) demonstrates that tephra 1B is younger than Crooked Creek tephra (fig. 3). Apparently uncontaminated samples of tephra 1B correlate moderately well with Augustine ash sample A88-11-5, which was collected by Begét (unpub. data) from proximal tephra layer "I" on Augustine Island ($\text{SC} = 0.94\text{--}0.96$), indicating that these samples could represent the same tephrafall. Our samples correlate slightly less positively with Begét (unpub. data) sample A88-7-5 from tephra layer "I" on Mt. Augustine ($\text{SC} = 0.93\text{--}0.95$). Both Begét samples correlate strongly ($\text{SC} = 0.98$). Begét and Kienle (1992) date proximal tephra layer "I" $>1,610 \pm 70$ ^{14}C yr B.P. (ETH-3826) and $<1,830 \pm 80$ ^{14}C yr B.P. (B-24775). Thus, tephra 1B could also conceivably be $>1,610 \pm 70$ and $<1,830 \pm 80$ ^{14}C yr old. There is good correlation between our five Kenai Lowland samples and the mean geochemistry of shards from layer "Y" in the Windy Creek area ($\text{SC} = 0.95\text{--}0.97$) (Pinney, 1993), indicating that these distant tephra layers record the same eruption of Mt. Augustine. Layer "Y" correlates well with Begét samples A88-11-5 and A88-7-5 ($\text{SC} = 0.97$ and 0.95 , respectively).

TEPHRA 1C

(MEAN $\text{SiO}_2 = 77.40 \pm 0.34$ PERCENT)

Tephra 1C is identified in four widely scattered sections in Kenai Lowland (fig. 8), and correlation within this small sample set is good to excellent ($\text{SC} = 0.93\text{--}0.98$) (table 8B). This volcanic ash has the high silica content that seems to typify tephra derived from Mt. Augustine (table 3).

Comparison of shard geochemistry of tephra 1C and Augustine samples collected by Begét (unpub. data) indicates that our four samples correlate best with Augustine sample A88-4-2 ($\text{SC} = 0.95\text{--}0.97$), slightly less well with sample 87A-16A ($\text{SC} = 0.93\text{--}0.97$), and are least compatible with sample A88-1-1 ($\text{SC} = 0.91\text{--}0.95$). In section 18 (fig. A18), tephra 1C (KL-123) is dated $>6,360 \pm 145$ ^{14}C yr B.P. (GX-18232) and $<6,801 \pm 55$ ^{14}C yr B.P. (GX-18225) (table 2, C4 and C5). These dates, the dating of tephra layer "I" on Augustine Island, and our apparent correlation of tephra 1B with layer "I" indicate that tephra 1C was probably deposited in Kenai Lowland before tephra 1B (fig. 3) and that the mixing of tephra 1B and 1C in section 53 (fig. A58) is most likely due to redeposition of tephra 1C.

TEPHRA 2?

(MEAN $\text{SiO}_2 = 76.61 \pm 0.35$ PERCENT)

A layer consisting of shards of several tephra was sampled at a depth of 2.6 m in a core collected in a peat fen just west of Moose River along the Sterling Highway (sheet 2, locality KEN-64; fig. A25). From this layer, a very small ($n = 3$) population of shards (KL-112p4) was separated, and we very tentatively and informally identify this small collection as tephra 2? (table 3). Also present are a few shards that we attribute to tephra 3 (KL-112p3), possible tephra 8? (KL-112p2), and an unnamed tephra (KL-112p1). We believe that the tephra in this complex layer are close to the same age (fig. 3) because mixing is unlikely in this situation. A radiocarbon date for peat 0.3 m below this layer in the core demonstrates that the mixed layer is $<7,725 \pm 210$ ^{14}C yr old (GX-18227) (table 2, C10). Because of their geochemical similarities ($\text{SC} = 0.95$), we speculate that tephra 2? could correlate with another population of glass shards (ATC-644Ap1) that is archived in the ATC, but we have no supportive mineralogic or stratigraphic evidence. The volcano that produced the ATC sample is not identified.

TEPHRA 3

(MEAN $\text{SiO}_2 = 75.29 \pm 0.37$ PERCENT)

Tephra 3 is identified in three sections—two in the Kenai-Sterling area and one near Homer (fig. 9). Chemical correlations between samples are excellent ($\text{SC} = 0.95\text{--}0.98$) (table 9A). This ash is mixed with other fine-grained tephra in sections 16, 25, and 73. As previously discussed, the setting and stratigraphy of section 25 indicate that tephra 3 (KL-112p3) is one of several tephra, including tephra 2? and 8?, that were erupted at about the same time after $7,725 \pm 210$ ^{14}C yr ago (GX-18227) (fig. A25) (fig. 3). The lower mixed layer in section 73 (fig. A79) is probably the result of the sifting of shards of a younger tephra 3 (KL-049p2) downward into an older layer of tephra 1C (KL-049p1). From stratigraphic evidence in section 72 (fig. A77) and (*Text cont'd. p. 45*)

and section 73 (fig. A79), we are convinced that tephra 1A and 3 are younger than tephra 1C. However, we are uncertain about the temporal relation of tephra 1A and 3 and about the relative ages of these two tephra and tephra 1B (fig. 3).

Among the tephra surveyed, sample KL-013p1 of tephra 3 correlates best with Augustine samples 87A-25A, A88-7-2, and A88-11-2 (Béget, unpub. data) (SC = 0.95–0.96). Our samples KL-048, KL-049p2, and KL-112p3 could also relate to those proximal Augustine samples but are apparently not from the same tephra fall (SC = 0.90–0.93).

TEPHRA 4

(MEAN SiO₂ = 75.21 ± 0.31 PERCENT)

Tephra 4 is identified with varying degrees of certainty in three sections in Kenai Lowland (table 3, fig. 10). Apparently unmixed shards of tephra 4 (KL-021) were recovered from section 39 (fig. A43), and shards (KL-111) with apparently strong affinity (SC = 0.96) (table 9B) are present in section 7 (fig. A7). However, a radiocarbon date of 11,905 ± 180 yr B.P. (GX-16521) for organic silt just

below sample KL-111 in that kettle filling makes this correlation questionable because of stratigraphic relations in other sections and because of apparently firm correlations elsewhere (unless there is a significant unconformity between the dated organic silt and sample KL-111). The setting in the floor of a kettle indicates that a significant interval of nondeposition or erosion is unlikely. Our best example of tephra 4 (sample KL-021) unquestionably overlies tephra 1A in section 39 (fig. A43) and so must be younger than tephra 1A (fig. 3). A small (n = 7) population of shards attributed to tephra 4 (KL-094p2) is mixed with obviously redeposited shards of tephra 1A (KL-094p1) in a layer that overlies apparently undisturbed tephra 1A in section 58 (fig. A63). This stratigraphic relation also demonstrates that tephra 4 is younger than tephra 1A. However, the similarity of sample KL-094p2 and samples KL-021 and KL-111 is low (SC = 0.91 and 0.93, respectively) (table 9B), indicating that they could be part of the same tephra set but are probably not from the same tephra fall.

KL-111	0.96	1.00		
KL-094p2	0.91	0.93	1.00	

Despite its apparently greater age, our sample KL-111 seems to correlate well with samples of the northeastern lobe of the Hayes tephra complex (ATC-636, ATC-637, and 88TL-CC of Begét, Reger, and others, 1991) from the upper drainage of Susitna River (SC = 0.95–0.96). Thus, there could be an unconformity below sample KL-111 (fig. A7). However, without supporting mineralogic evidence, we remain skeptical of this correlation. The northeastern lobe of the Hayes tephra complex has been firmly dated at close to 3,700 ¹⁴C yr B.P. (Riehle, 1985, 1994; Riehle and others, 1990; Begét, Reger, and others, 1991). Sample KL-111 also seems to correlate with samples of both the rhyodacite Devil tephra (SC = 0.95), dated at >1,400 ¹⁴C yr B.P. and <1,900 ¹⁴C yr B.P. (Dille, 1988), and the lower member of the Watana tephra set (SC = 0.96), dated >1,850 ¹⁴C yr B.P. and <2,800 ¹⁴C yr B.P. (Dille, 1988). Mineralogical comparisons may resolve this dilemma. Samples KL-021 and KL-094p2 also seem to correlate with the samples from the upper Susitna River drainage (SC = 0.93–0.95), but without supporting mineralogic data, we remain unconvinced.

Another volcanic ash that is possibly correlative with tephra 4 is the ash layer represented by samples A-T1 and B-T1 from peats on low terraces of the Kaslof River and Kenai River, respectively (Combellick and Pinney, 1995). Their samples are geochemically most like Hayes proximal sample 23-A of Riehle (1985) (SC = 0.94–0.95) and could have been deposited as part of the same eastward-moving tephrafall. Combellick and Pinney (1995) dated samples A-T1 and B-T1 at an average age of 3,530 ± 70 ¹⁴C yr B.P., which at 1 σ is identical to the average age of 3,650 ± 150 ¹⁴C yr B.P. reported by Riehle (1985) for the Hayes tephra complex in the region. Comparisons of glass chemistry indicate that sample KL-111 most likely correlates with samples A-T1 and B-T1 (SC = 0.97 and 0.98, respectively); sample KL-021 probably does also (SC = 0.96). However, sample KL-094p2 is less likely to be closely correlative (SC = 0.92–0.93).

Our tephra 4 data leave us in a quandary about correlative tephra, but we tentatively believe that tephra 4 is part of the widespread tephra complex that was erupted from Hayes volcano about 3,700 ¹⁴C yr ago (fig. 3).

TEPHRA 5

(MEAN SiO₂ = 73.88 ± 0.58 PERCENT)

We recovered populations of shards attributed to tephra 5 mixed with shards of other tephra in four sections distributed in a narrow, northeast-trending belt in Kenai Lowland (table 3, fig. 11). However, we are not confident that all of these populations represent the same tephrafall; instead they may be part of the same tephra set (SC = 0.92–0.95) (table 10A). As previously discussed, tephra 5 (KL-086p2) and Lethe tephra (KL-086p3) are redeposited and mixed with a younger Crooked Creek tephra (KL-086p1) in section 66 (fig. A71). The degree of redeposition of tephra 5 (if any) is uncertain in section 11 (fig. A11), section 41 (fig. A45), and section 55 (fig. A60), but we are inclined to think that tephra 5 is probably not significantly reworked there. On the basis of previously stated arguments (see Lethe tephra discussion) and stratigraphic relations in sections 41 and 55, we tentatively conclude that tephra 5 slightly postdates Lethe tephra in Kenai Lowland (fig. 3).

Among the tephra surveyed, our sample KL-015p2 correlates best with sample R-J (Riehle, 1985) from Mt. Redoubt (SC = 0.96). Our other three samples are less likely to have been erupted from that volcano (SC = 0.92–0.93).

TEPHRA 7?

(MEAN SiO₂ = 73.13 ± 0.41 PERCENT)

We isolated a single, small population of four shards (KL-013p2) from section 16 (fig. A16) that we very tentatively and informally call tephra 7? (table 3). These shards are mixed with a small population (n = 8) of shards that we attribute to tephra 3. Because the degree of redeposition of both tephra is uncertain in this section, we

Table 10. Similarity-coefficient matrices for samples of tephra 5 and 13 collected in Kenai Lowland

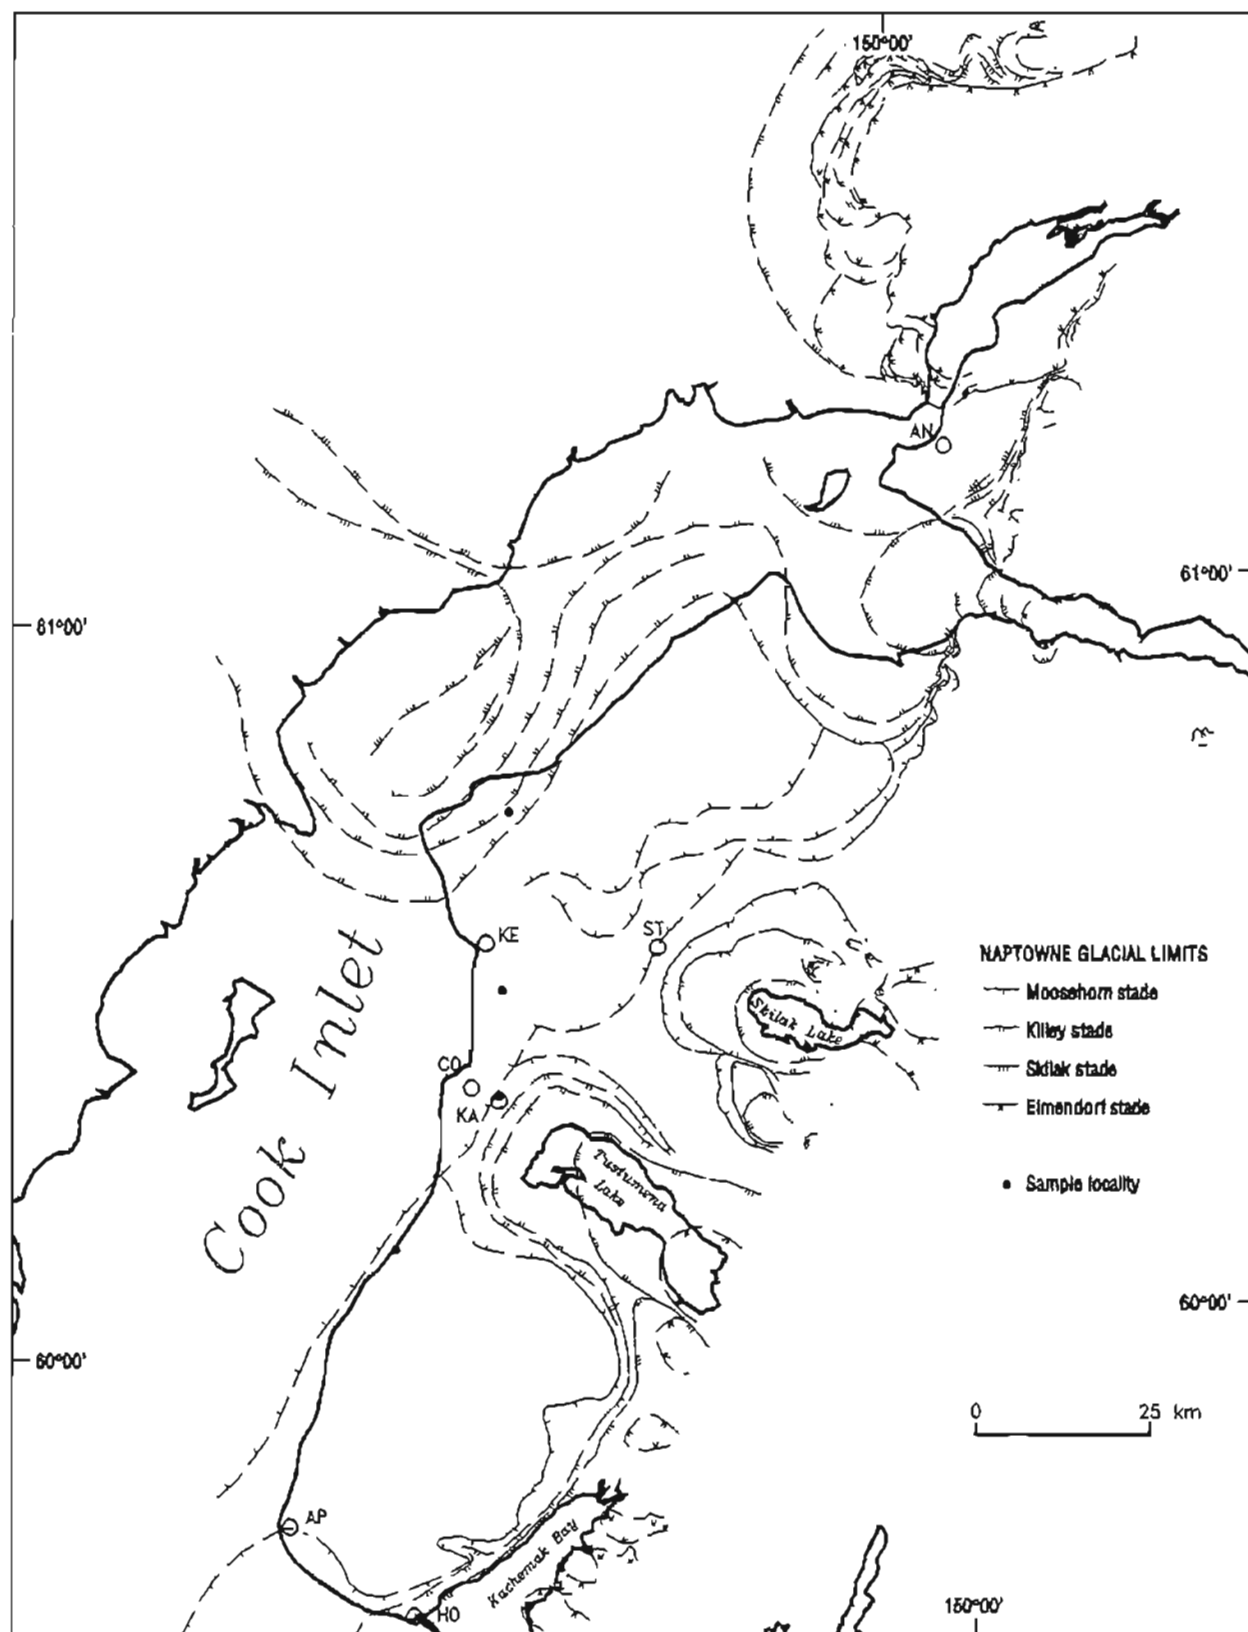

Figure 11. Distribution of tephra S samples ($n = 4$) in Kenai Lowland relative to former limits of the Naptowne glaciation. Geographic localities: AN = Anchorage; AP = Anchor Point; CO = Cohoe; HO = Homer; KA = Kasilof; KE = Kenai; ST = Sterling.

cannot comment with certainty on their relative ages. However, if our few shards actually represent a legitimate tephra, their major-oxide content is comparable to the geochemistry of shards in samples R-EE and R-N (Riehle, 1985) and ATC sample ATC-644 ($SC = 0.95-0.97$). Our sample conceivably could also correlate with the Oshetna tephra ($SC = 0.95$), which dates $>5,200$ ^{14}C yr B.P. and $<5,900$ ^{14}C yr B.P. (Dille, 1988) (fig. 3). The volcano that produced these samples is not identified.

TEPHRA 8?

(MEAN $SiO_2 = 71.24 \pm 0.45$ PERCENT)

As previously discussed, from a depth of 2.6 m in a core (section 25, fig. A25) taken at locality KEN-64 (sheet 2) we isolated a small population ($n = 5$) of shards (KL-112p2) that we very tentatively and informally call tephra 8? (table 3). The layer of mixed tephra there was deposited after $7,725 \pm 210$ ^{14}C yr B.P. (GX-18227), but this is probably not a close maximum age. The setting of section 25 in a peat fen makes redeposition of tephra 8? unlikely. The mixing of this fine-grained volcanic ash with tephra 3 indicates that both are essentially coeval (fig. 3).

Assuming that the geochemistry of these few shards is representative of tephra 8?, we compared it with other tephra in the region. The best match ($SC = 0.96$) was achieved with sample R-5-E from Mt. Redoubt (Riehle, 1985).

TEPHRA 12?

(MEAN $SiO_2 = 74.69 \pm 0.23$ PERCENT)

From section 55 (fig. A60), we collected a very small population ($n = 3$) of shards (KL-129p2) of a tephra that we very tentatively and informally call tephra 12? (table 3). These shards are mixed with a small population ($n = 7$) of shards that we attribute to tephra 5 (KL-129p1). Because the degree of reworking is uncertain in this sand-dune setting, we are uncertain of the relative ages of tephra 5 and 12? (fig. 3), but we are convinced that both are younger than the Lethe tephra (KL-128), which is stratigraphically lower in the section (fig. A60).

Our small population of tephra 12? shards compares geochemically with shards of a single sample (R-T) from Mt. Redoubt (Riehle, 1985) ($SC = 0.95$).

TEPHRA 13

(MEAN $SiO_2 = 64.69 \pm 0.22$ PERCENT)

From four layers of mixed tephra in three sections in Kenai Lowland (fig. 12), we isolated four small populations of shards that we informally call tephra 13 (table 3). These shard populations are geochemically distinct and, except for sample KL-095p3, are chemically very similar (table 10B). We believe that samples KL-032p3, KL-050p2, and KL-095p2 represent a single tephra fall ($SC = 0.96-0.97$) and that sample KL-095p3 is probably part of

the same tephra set—if not part of the same tephra fall ($SC = 0.93-0.96$).

Although our samples apparently correlate with Oshetna 1 tephra in the upper Susitna River drainage (ATC, unpub. data) ($SC = 0.95-0.97$), stratigraphic relations cause us to be skeptical. The Oshetna tephra is dated at $>5,200$ ^{14}C yr B.P. and $<5,900$ ^{14}C yr B.P. (Dille, 1988), considerably younger than the probable age of tephra 13 in the western Kenai Lowland (fig. 3). Stratigraphic relations in section 22 (fig. A22) indicate that tephra 13 is likely to be older than Crooked Creek tephra, which we date at $>7,725 \pm 210$ ^{14}C yr B.P. and $<8,375 \pm 210$ ^{14}C yr B.P. (fig. A25).

MIDDLE QUATERNARY TEPHRAS

During our investigations of the Goose Bay peat at the type section (sheet 1, locality ANC-22), we encountered numerous thin, discontinuous layers of fine-grained volcanic ash that did not seem to be temporally significant (fig. A3). However, we documented two layers of tephra that are potentially useful for dating and correlation.

GOOSE BAY TEPHRA

(MEAN $SiO_2 = 65.74 \pm 1.03$ PERCENT)

Just above the middle of the Goose Bay peat is a relatively thick, pinkish-gray tephra that has consistently cropped out of the bluff face during the past 10 years that we have watched the cliff recede in response to wave attack. This tephra was severely deformed by glacier overpressures during the Naptowne glaciation and probably during previous ice advances (Rieger and others, 1995). We informally call this distinctive tephra layer the Goose Bay tephra (fig. A3). Of two samples that we collected from this fine-grained volcanic ash, KL-027 is apparently not significantly contaminated by shards from other tephra (table 3). However, KL-081 contains two populations of shards that are chemically distinct. KL-027 apparently correlates with KL-081p2 ($SC = 0.97$), indicating that both samples represent the same tephra (table 11A). KL-081p1 is chemically less similar to KL-027 ($SC = 0.94$) and is even less like KL-081p2 ($SC = 0.92$), perhaps as a result of multiple eruptions from the same volcano during conditions of changing magma chemistry. We know of no correlative tephra, including the widespread, 141-ka Old Crow tephra in interior Alaska (Westgate and others, 1983, 1990; Westgate, 1988; Begét, Edwards, and others, 1991).

$^{40}Ar/^{39}Ar$ dating of the Goose Bay tephra by the laser method produced a three-sample (composite) isochron age of 378 ± 0.67 ka (Lager, 1994, written commun.). We believe that this age is the most reliable result of several attempts that we have made in the past to date the Goose Bay peat. A previous, questionable attempt to date the Goose Bay tephra by fission-track counts of 10,000 apatite grains produced a calculated mean age of 92.1 ka with a

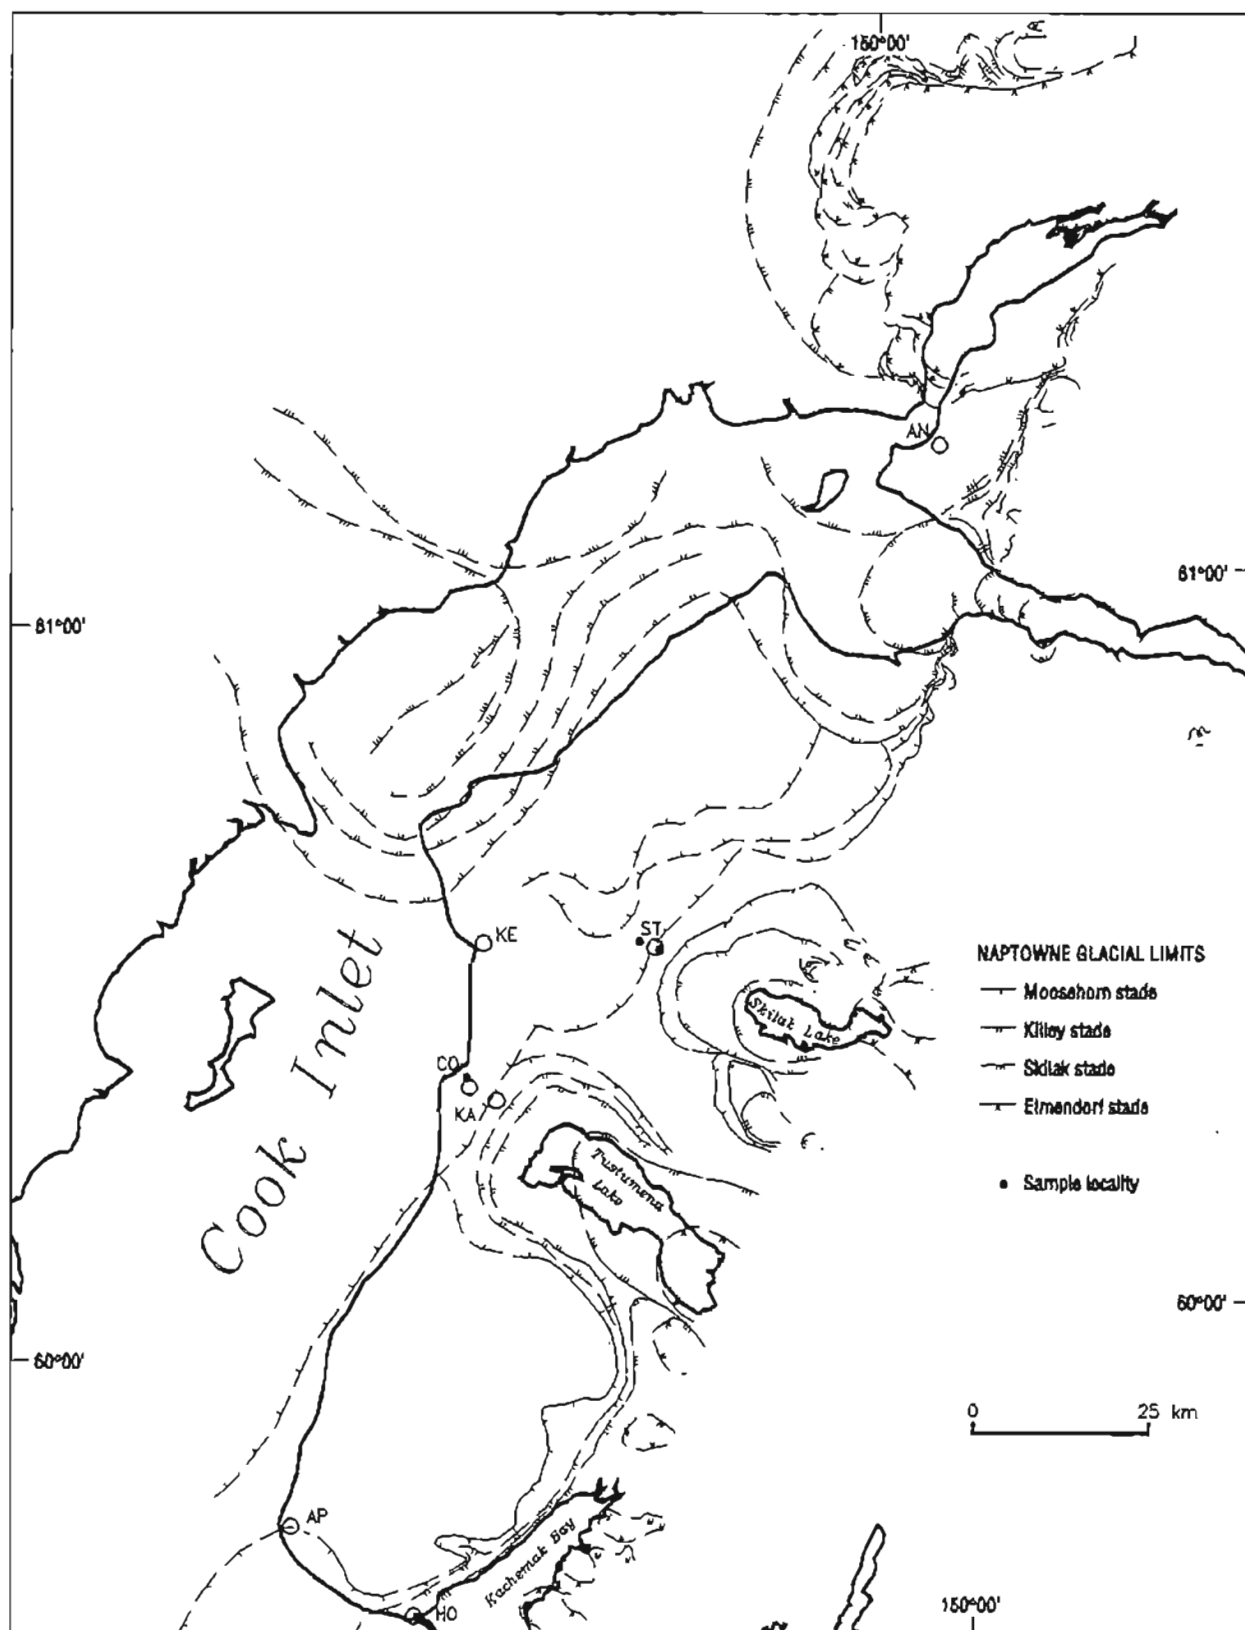

Figure 12. Distribution of tephra 13 samples ($n = 3$) in Kenai Lowland relative to former limits of the Naptowne glaciation. Geographic localities: AN = Anchorage; AP = Anchor Point; CO = Cohoe; HO = Homer; KA = Kasilof; KE = Kenai; ST = Sterling.

Table 11. Similarity-coefficient matrices for samples of Goose Bay tephra and Stampede tephra collected from the type section of the Goose Bay peat, locality ANC-22 (sheet 1)

A. Goose Bay tephra			
	<u>KL-027</u>	<u>KL-081p1</u>	<u>KL-081p2</u>
KL-027	1.00		
KL-081p1	0.94	1.00	
KL-081p2	0.97	0.92	1.00
B. Stampede tephra			
	<u>KL-083</u>	<u>KL-082</u>	<u>KL-025</u>
KL-083	1.00		
KL-082	0.99	1.00	
KL-025	0.98	0.97	1.00

95-percent certainty that the actual age is less than 171.2 ka (Riehle, 1989, oral commun.; Zimmerman, 1990, written commun.). However, we could obtain few details on how this result was obtained, so we remain unconvinced that the calculated mean age is reliable. Thermoluminescence analyses of organic silts above and below the Goose Bay tephra in the section produced dates of $181,300 \pm 18,500$ yr B.P. and $175,100 \pm 11,500$ yr B.P., respectively (fig. A3), but we consider these results to be unreliable because of uncertainties in the amount of time that the local sediments were saturated. As previously discussed, radiocarbon dating was also unsuccessful because the peat is older than the maximum range of the method.

If the $^{40}\text{Ar}/^{39}\text{Ar}$ date is reliable, the Goose Bay peat is

middle Pleistocene in age as are the underlying Knik till and associated deposits (fig. A3). This means that the Knik glaciation is much older than envisioned by previous workers (Karlstrom, 1957, 1964; Miller and Dobrovolsky, 1959). The Knik till and overlying lacustrine sediments are paleomagnetically normal, indicating that they are younger than 730,000 yr (fig. A3).

STAMPEDE TEPHRA

(MEAN $\text{SiO}_2 = 77.50 \pm 0.23$ PERCENT)

Stratigraphically underlying the Goose Bay tephra in the lower part of the Goose Bay peat is a thin, light-colored, high-silica tephra couplet from which we collected samples KL-025, KL-082, and KL-083 (table 3, fig. A3). The presence of the two closely spaced layers that form the couplet indicates that two tephrafalls were likely involved, but the very consistent geochemistry among the three samples ($\text{SC} = 0.97\text{--}0.99$) indicates that they almost certainly came from the same source (table 11B).

Begét (1992, oral commun.) first correlated this tephra with his Stampede tephra in interior Alaska (Begét and Keskinen, 1991). Comparisons of the glass geochemistry of our samples with Stampede tephra samples ATC-669, ATC-670, and ATC-685 support this correlation ($\text{SC} = 0.96\text{--}0.99$). Counts of a small number of glass-coated ferromagnesian grains in our samples (table 12) also compare favorably with counts by Begét and Keskinen (1991, table 4), although they differ slightly. We document slightly less hornblende and did not find biotite or rutile. We believe that our high similarity-coefficient values and our very similar ferromagnesian counts are permissive if not conclusive evidence for the correlation suggested by Begét.

Table 12. Abundances of glass-coated ferromagnesian grains in three tephra samples from the lower Goose Bay peat, locality ANC-22 (sheet 1)

A. Actual grain counts					
Tephra sample	cpx	Number of grains counted ^a			Frequency (%) cpx:opx:hbd
		opx	hbd	Total	
KL-025	2	15	3	20	10:75:15
KL-082	5	15	12	32	16:47:37
KL-083	4	6	8	18	22:33:45
TOTAL	11	36	23	70	—
B. Relative-abundance classes^b					
Sample	cpx	opx	hbd		
KL-025	S	A	S		
KL-082	S	C	C		
KL-083	S	C	C		

^aAbbreviations: cpx = clinopyroxene; opx = orthopyroxene; hbd = hornblende.

^bClasses indicate relative grain contents in the populations counted: A = abundant (>50 percent); C = common (30–50 percent); S = scarce (10–30 percent).

Assuming that the $^{40}\text{Ar}/^{39}\text{Ar}$ age of the Goose Bay tephra is correct and that correlation of the lower tephra couplet with the Stampede tephra is valid, evidence in the Goose Bay section demonstrates that the Stampede tephra is slightly older than 378 ± 0.67 ka but is middle Quaternary in age (fig. A3). Deformation of Stampede tephra during the Lignite Creek glaciation in Nenana River valley (Begét and Keskinen, 1991) had to occur later in middle Quaternary time in the type area of the Lignite Creek glaciation (Thorson, 1986).

FOSSILS

We collected fossils from late Quaternary deposits in the eastern and northern Cook Inlet region with the intent of dating the sediments and gathering information on depositional conditions. A total of 12 macrofossil assemblages were collected from the Bootlegger Cove Formation (BCF) (table 13).

MIDDLE INLET COLLECTIONS

BCF collections F4 and F5 from the Kenai-Kalifornsky area along the eastern shore of Cook Inlet are depauperate in species compared to collections from upper Cook Inlet. Generally, only scattered, broken, calcareous barnacle plates were found, although rare whelk shells were recovered at Kenai. Large barnacle plates are identified as *Balanus evermanni* in the Kenai section (fig. A20). This robust barnacle is typically found living in deep marine waters in Prince William Sound, where tidal currents are

strong (Foster, 1994, oral commun.). A sample of silty sand and one of pebbly diamicton from the Kenai section were submitted for microfossil analysis, including determination of their foraminiferal, ostracod, and diatom contents. The sand sample was barren, and in the diamicton a single *Diatoma* sp. was identified (Micropaleo Consultants, Inc., 1993, written commun.). We believe that this specimen is probably recycled from Tertiary rocks in the Cook Inlet Basin and has no Quaternary significance. The stratigraphy at Kenai indicates that *B. evermanni* lived on the surface of a sandy submarine fan in front of a tidewater glacier. This fan was overridden when the glacier advanced south-eastward, and the saturated fan sediments were folded and faulted (fig. A20) when the base of the tidal glacier came into contact with the inlet bottom. The tidal range is up to 9 m at Kenai, and we speculate that contact occurred during low tides. Dating of the *B. evermanni* plates demonstrates that the tidal glacier was at Kenai shortly after $16,480 \pm 170$ ^{14}C yr B.P. (tables 2 and 14), during the Killey stage of the Naptowne glaciation (Reger and Pinney, 1996). This important section also demonstrates that a marine connection existed between middle Cook Inlet and the North Pacific Ocean as early as 16,500 ^{14}C yr ago.

The meager BCF macrofauna (F5) from the bluff at Kalifornsky consists of rare, broken barnacle plates (table 13), which we date at $16,000 \pm 150$ and $16,090 \pm 160$ ^{14}C yr B.P. (tables 2 and 14). Schmoll and Yehle (1983, 1986, loc. B5) and Schmoll and others (1984, loc. B7) reported a date of $16,340 \pm 140$ ^{14}C yr B.P. (W-4937) for *Balanus* sp. plates from silt and clay assigned to BCF in the Kalifornsky beach bluff but did not provide specific

coordinates. We assume that their locality is the same as our section 45 (fig. A50) or close to it because this is the only BCF section in which we found barnacle plates along Kalifornsky beach. From section 45 we submitted five samples of sandy mud for analysis of their foraminifera, ostracod, and diatom contents in an effort to reconstruct conditions during BCF deposition. No ostracods or diatoms were found in any of the samples. Only one sample contained rare *Elphidium incertum* (three juveniles) and *Bucella cf. frigida* (two juveniles) (Micropaleo Consultants, Inc., 1991, written commun.). From this preliminary test we conclude that very cold glacioestuarine conditions of variable turbidity and salinity probably existed in middle Cook Inlet about 16,000 ¹⁴C yr ago. The stratigraphy in section 45 (fig. A50) indicates that debris-laden icebergs probably floated at least as far south in Cook Inlet as the Kalifornsky area 16,000 ¹⁴C yr ago and, as they melted, they rained silt, sand, and occasional dropstones onto the inlet floor, burying the barnacle plates. Like at Kenai, these plates were not found in growth positions but were probably swept along the bottom by strong tidal currents. Soft-sediment deformation of laminated clayey silts at the base of the bluff near the section indicates that the icebergs dragged their keels during low tides. Overturning of folds toward the southeast indicates that the icebergs were moving from the northwest at the time. However, this deformation does not necessarily reflect the ultimate source of the glacier ice; it could result from berg movement in response to tidal currents or wind, or both.

From the extensive exposure near the mouth of Kasilof River (sheet 2, loc. KEN-117), we submitted two samples of pebbly diamicton for microfossil analysis. Both samples

contained very rare to rare diatoms identified as *Tetracyclus cf. lacustris*, *Diatoma?* sp., *Pinnularis* sp., and *Melosira granulata* (Micropaleo Consultants, Inc., 1993, written commun.) (fig. A57). All are freshwater diatoms. Plafker (1956) found *Tetracyclus*, *Pinnularis*, and *Melosira* in diatomaceous earth of Holocene age north of Kenai, where *Melosira* is particularly abundant. We believe that the section at the mouth of Kasilof River was deposited in a very cold freshwater conditions and could slightly predate the section at Kalifornsky.

UPPER INLET COLLECTIONS

Macrofossils were collected from the BCF at 10 sites in the bluffs along Knik Arm and Turnagain Arm (table 13). These collections are dominated by up to six species of pelecypods, and minor elements include two species of gastropod and unidentified barnacle plates. With the exception of *Mya truncata* valves in collection F11 (table 13), which were collected in pairs in growth position in a silty clay with numerous pebble dropstones, we cannot verify that our macrofossils lived where they were found. Indeed, we postulate that, for a brief time after their deaths, most faunal remains would have been transported from their living sites on the bottom of upper Cook Inlet by strong tidal currents. Collections of unidentified mollusk shells from the macrofossil-rich zone in upper BCF in the Knik Arm and Turnagain Arm area are reported by Schmoll and others (1972), and a single collection of unidentified shells is reported from the thick BCF exposure near the mouth of Beluga River in western upper Cook Inlet (sheet 5, loc. TYO-7) (Schmoll and others, 1984; Schmoll and Yehle,

1986). Our BCF fauna from upper Cook Inlet is rich in species compared to the modern *Macoma balthica* fauna, which has probably existed in upper Cook Inlet for at least 6,000 ^{14}C yr (Bartsch-Winkler and others, 1983; Bartsch-Winkler and Schmoll, 1992; Combellick and Reger, 1994, loc. 92-20). With the exception of *M. balthica*, extant species of pelecypods represented in the BCF fauna are not known north of Kachemak Bay in lower Cook Inlet (Science Applications, Inc., 1977; Baxter, 1983; Foster, 1991; Kimker, 1994, oral commun.). There and in western lower Cook Inlet, they live in clear, locally turbulent marine waters. *Hiatella arctica*, *Macoma balthica*, *Macoma calcaria*, and *Mya truncata* persist in a variety of habitats from intertidal and sublittoral zones to depths of hundreds or even thousands of meters (Baxter, 1983; Foster, 1991). *Macoma balthica* has a great tolerance for both turbid waters and a broad range of salinities and is the only species of clam that tolerates the brackish, turbid conditions on tidal flats in upper Cook Inlet. *M. calcaria* also tolerates a broad range of salinities but lives in less turbid waters (Foster, 1994, oral commun.). Thus, the relatively complex macrofauna indicates that, at least during deposition of the macrofossil-rich zone of the upper BCF, waters in upper Cook Inlet were probably less turbid and more saline than the estuarine waters there today, even though the widespread presence of dropstone-rich facies indicates the presence of tidewater glaciers (Reger and others, 1995). We speculate that conditions in upper Cook Inlet then were similar to present conditions in some of the fjords along the coast of southcentral and southeastern Alaska, except that the waters were more tide dominated.

Schmidt (1963) first reported marine foraminifera and ostracods from the shell-rich zone on the south side of Knik Arm near locality ANC-43 (sheet 1). Freshwater microfossils are reported from several BCF zones in the Anchorage area (Schmoll and Yehle, 1986). Most workers agree that the microfauna in various parts of the BCF indicate widely variable conditions of salinity, but no systematic, intensive study of the distribution of BCF microfossils has been published.

Dating of the BCF proper in upper Cook Inlet is restricted to the shell-rich zone in the upper part of the formation. Shells of marine mollusks from this zone range in age from a minimum of $13,470 \pm 120$ ^{14}C yr B.P. (table 14, F11) to $14,900 \pm 400$ ^{14}C yr B.P. (table 2, C79). Schmoll and Yehle (1986) reported an age of $14,350 \pm 200$ ^{14}C yr B.P. for marine mollusk shells from BCF near the mouth of Beluga River (table 2, C78). Organic silt at the base of freshwater peat overlying BCF on Fire Island is $12,250 \pm 140$ ^{14}C yr old (table 2, C57), providing a firm minimum age for BCF in the upper Cook Inlet region.

SOIL PROFILES

Soil development was considered important evidence

for assigning ages to moraines in the Cook Inlet region by Miller and Dobrovolsky (1959) and Karlstrom (1964). To evaluate the validity of their faith in this relative-age parameter, we briefly examined soil profiles on Naptowne moraines in three different parts of the region. The ages of these moraines were determined by physiographic and stratigraphic evidence other than soils. To minimize variations in rates of soil development due to different topographic position (Birkeland and others, 1991a; Berry, 1994), we measured profiles on flat summits of large moraines, except for the rounded crest of the small 9,900-yr-old moraine in Turnagain Pass (table A9).

The soils that are developed on the moraines in the areas we studied are spodosols. During profile formation (podzolization), leaching by organic acids results in development of a subsurface spodic (B) horizon by the down-profile translocation of a complex of iron, aluminum, manganese, clays, and organic matter (Rieger, 1983; Birkeland, 1984). This horizon is enriched in clays and iron sesquioxides or humic iron sesquioxides that initially result in a yellowing of the B horizon and later in reddening and brightening as more and more of these compounds accumulate as grain coatings, bridges, and cements. Where leaching is advanced in the upper part of the spodosol profile, removal of iron and aluminum by fulvic and other humic acids produces a very light colored albic (E) horizon just beneath the mat of surface vegetation.

STERLING PROFILES

Our objective in documenting soil profiles in the type area of the Naptowne glaciation (Karlstrom, 1964) was, if possible, to establish a Naptowne chronosequence that we could relate to the entire Kenai Lowland.

The youngest profile, S3, was measured in a pit close to section 44 (fig. A48) at 89 m elevation on the flat crest of the type Skilak moraine (sheet 2, loc. KEN-101). The section exposed 54 cm of loess overlying 8 cm of sandy pebble-gravel till of Skilak age. There is some local frost disturbance in the loess, and pebbles are thinly capped with silt and clay, demonstrating some minor downward migration of silt and clay through the profile. The B horizon is as thick as 6 cm (fig. A49, table A5). Depth to the bottom of the B horizon is 17 cm. The moist field color of the Bs subhorizon is a light olive brown, and there is a slight increase in the content of silt and clay over subhorizon Bw? (fig. A49). Both silt and clay gradually decrease downward through the profile.

The intermediate profile, S1, was measured at 101 m elevation on the flat crest of the type Killey moraine (sheet 2, loc. KEN-79). Our soil pit was dug about 10 m south of section 31 (fig. A33), and the eolian sand layer is missing. Instead, 28 cm of loess overlies a sandy and pebbly till of Killey age. In this profile, silt-clay caps are weakly developed on pebbles through the entire section,

demonstrating the presence of illuvial silt and clay in the profile (fig. A34). Differentiation of the B subhorizons is slightly more progressed in the Killey-age profile than in the Skilak-age profile, and they are slightly thicker (fig. 13). Comparison of the Bs horizons in both soils demonstrates that the hue in the Killey-age profile (10YR) is slightly more reddish than in the Skilak-age profile (2.5Y) (tables A4 and A5). Profile S1 has a markedly higher clay content and has the highest content of visible volcanic ash of the three sections studied.

The oldest Naptowne-age profile (S2) was documented at 91 m elevation on the flat crest of the type Moosehorn moraine (sheet 2, loc. KEN-80). The test pit was dug about 5 m from the pit in which section 32 (fig. A35) was measured. The loess cover is 13 cm thinner in the soil test pit. Silty pebble coatings are present throughout the section (fig. A36). There is incipient ped development in horizon Bs, which definitely has a more reddish hue (5YR) than the Bs horizon in the Killey-age profile (10YR) (tables A3 and A4). However, the bottoms of the B horizons are at about the same depth in both soils.

These three profiles are located in equable conditions of loess rain, materials (same till source), climate, vegetation, and there has been a history of fairly frequent wildfires. The main difference between the profiles should be the time of soil formation. However, we are not satisfied that our three Naptowne-age profiles constitute a reliable chronosequence. The Moosehorn-age profile (S2) appears to be very young for a soil that has been developing for about 18,000 ^{14}C yr (Reger and Pinney, 1996). We suspect that this profile has been truncated at some time in the past and is more representative of a profile that is intermediate in age between a Skilak profile and a Killey profile. This complex history may explain the inconsistent development of soil parameters among the three profiles (fig. 13). The magnitude and intensity of frost disturbance of the loess especially is an unevaluated condition that complicates profile development. The presence of at least one tephra layer in the Bw horizon of the Killey-age profile (table A3) and the likely presence of tephra in loess in the other profiles also complicates profile interpretation. Clearly, more profiles need to be documented and evaluated before a reliable chronosequence can be developed.

KACHEMAK BAY PROFILES

Profile S4 was documented in a test pit at 123 m elevation on the flat crest of the lobate moraine built by the Moosehorn advance of the Kachemak Bay lobe just south of Anchor River (Reger and Petrik, 1993) (sheet 3, loc. SEL-7). This pit was dug near section 72 (fig. A77) and exposed 62 cm of loess, tephra, and redeposited tephra over sandy drift (fig. A78). The E horizon is 2 to 10 cm thick, and the B horizon is strongly differentiated with Bw,

Bs, and Bhs subhorizons that range in moist colors from reddish brown to very dusky red (table A6). However, this color change is complicated by the presence of volcanic ash in subhorizon Bs. In fact, the entire profile, with its multiple soils and numerous tephra, is complicated and difficult to interpret.

We measured profile S5 at 342 m elevation on the crest of the lateral moraine of the Moosehorn advance of the Kachemak Bay lobe (sheet 3, loc. SEL-13). The test pit was excavated close to the pit where we had earlier measured section 93 (fig. A79). The soil pit exposed 61 cm of loess and tephra over sandy drift, but the profile, although complicated by the presence of a buried soil, is simpler than profile S4. The E horizon in profile S5 is discontinuous and up to 3 cm thick (fig. A80, table A7). Development of the B subhorizons is well advanced in both the surface and buried soils. In the buried soil, the Bhs subhorizon has a very dusky red moist color, and there is no recognized Bw subhorizon. In the surface soil, the Bhs subhorizon is also very dusky red, and the Bw subhorizon is dark reddish brown.

Comparison of the two soil profiles studied near Homer with soil development in the type area of the Naptowne glaciation is complicated by a higher rate of loess influx (including significant volcanic effluents), buried soils, different vegetation, and a much wetter climate with cloudier, slightly cooler summers in the Homer area. Wildfire frequency in the coastal rainforest, which is dominated by Sitka spruce, is undoubtedly much lower than in the mixed woodland of black and white spruce and hardwoods, which indicates a modified continental or continental climate in the Sterling area. The higher production of organic acids in the Homer area, due to greater rainfall and a more persistent, lush vegetation, is indicated by (a) the presence of Bh and Bhs subhorizons in the Moosehorn-age soils there and (b) the absence of these subhorizons in the Moosehorn profile (S2) in the Sterling area.

TURNAGAIN ARM PROFILES

We recorded soil profile characteristics at two localities in the vicinity of Turnagain Arm. Soil profile S6 (fig. A83, table A8) was measured at an elevation of 25 m on the flat crest of the Elmendorf-age Bird Creek moraine, which is close to 14,000 ^{14}C yr old (Reger and others, 1995) (sheet 4, loc. SEW-2). In this profile, podzolization is slightly more advanced than in the slightly older Skilak-age profile (S3) in the Sterling area. In the Elmendorf-age soil, the Bs subhorizon is 5 cm thicker and slightly redder (table A8) than the Bs subhorizon in the Skilak-age soil (table A5)—yet the parent tills for both soils are derived from the same terrane and have an unweathered olive-

Figure 13. Comparison of soil profiles developed on type Moosehorn, Killey, and Skilak moraines in the type area of the Naptowne glaciation. Numbers for silt and clay content given to 0.1 percent to show values <1 percent. Soil horizon terminology slightly modified from system proposed by Birkeland and others (1991b).

gray color. The Bs subhorizon in profile S6 could be disturbed by frost action.

Soil profile S7 (fig. A84, table A9) was documented at an elevation of 297 m on the crest of a small 9,900-yr-old moraine of latest Elmendorf age in Turnagain Pass in the Kenai Mountains (sheet 4, loc. SEW-12). This is the youngest profile that we documented. Development of the spodic horizon is very advanced, as indicated by significant reddening and darkening of the B subhorizons compared to the olive gray of the parent till (table A9). The degree of change in hue in the Bhs and Bh subhorizons in profile S7 exceeds the greatest color change in the oldest Moosehorn-age soil in the Sterling area, and the B horizon is 18 cm thicker (table A3). Silt and clay caps are present in the Bhs, Bw, and Cox subhorizons. In the Bw subhorizon, the caps are a very bright dark-reddish brown and are moderately thick. Mottling of the Cox subhorizon could be due to frost action.

Soil horizons are strongly differentiated in profiles S6 and S7, which are younger than the profiles we measured on older moraines in Kenai Lowland. In our opinion, this strong horizon development reflects the very moist maritime climate of the Kenai Mountains. Burned spruce stumps at the site of profile S6 and small-diameter trees in the mixed conifer and hardwood woodland there are evidence of a fairly recent wildfire. Well-developed Bh and Bhs horizons demonstrate that humic-acid production has been intense beneath the subalpine vegetation at the site of profile S7, which is the younger of the two sites. Fire frequency at profile S7 was undoubtedly very low—if not zero—during the Holocene, so plant cover has probably remained generally undisturbed in Turnagain Pass. Precipitation increases dramatically with elevation in Alaska's coastal mountains, so there was almost certainly adequate moisture for producing considerable fulvic acid in Turnagain Pass.

DISCUSSION

Comparison of hue and chroma values for horizons in profiles on the type Skilak, Killey, and Moosehorn moraines (tables A3-A5) clearly shows progressive reddening (changes of one to four hue units) and brightening (changes of one to six chroma units). As previously stated, interpretation of these values in two Moosehorn-age profiles in the Kachemak Bay area (tables A6 and A7) is difficult because of the complex stratigraphy and complicated histories of soil formation and loess deposition. However, differences of up to five hue units and five chroma units in horizons compared to the parent material indicate significant profile development. Two profiles of latest Wisconsin age in the vicinity of Turnagain Arm (tables A8 and A9) show remarkable reddening (changes of two to five hue units) and brightening (changes of one to five

chroma units) despite their youth relative to other Naptowne profiles. Clearly, rubification is locally progressive in older soil profiles of Naptowne age. However, we did not record dry soil color and could not calculate rubification indexes (Harden, 1982) for the seven profiles that we document. Complex local stratigraphy and the presence of numerous tephra in the profiles also frustrated our calculations of profile development indexes (Harden, 1982).

Our documentation of soil profiles in these three areas and casual observations of soils and vegetation elsewhere in the study region convince us that significant environmental gradients have existed in the past and still persist, even locally. These gradients affect rates of soil formation and seriously complicate the use of soils to date landforms. Because climate and vegetation are relatively continental in the area of the type Naptowne moraines and relatively maritime near the Cook Inlet coast and because annual precipitation increases with elevation (especially in the Kenai Mountains), rates of soil development are faster near the coast and at higher elevations than in low-level inland sites. Moraines that are known to be of the same age based on physiographic and stratigraphic relations bear very different soils in different areas.

TILL-SOURCE STUDY

During the last major glaciation of Cook Inlet, ice entered the basin from centers of snow accumulation in the surrounding uplands, including the Kenai Mountains, the Chugach Mountains, the Talkeetna Mountains, and the Alaska-Aleutian Ranges (Schmoll and others, 1984, fig. 5). Sources of the resulting glacial deposits are obvious in the mouths of glaciated valleys or in moraines that are clearly related to nearby uplands. However, the dynamics of former glaciers were very complicated in parts of the upper Cook Inlet trough—for example, in the Swanson River-Moose River area—where ice could have come from several directions, depending on glaciological conditions in the uplands or conditions in the area of deposition. As a further complication in these areas, there likely was overriding and reworking of deposits from a given source by ice from other sources as conditions changed in ice-accumulation areas and in the basin of deposition.

Karlstrom (1964, plates 3 and 4) first plotted the distributions of moraines in the Cook Inlet trough and showed his interpretation of the extents of ice lobes from different sources by designating interlobate and other moraines. Our model of the Naptowne glaciation in this region evolved primarily from the study of landform distribution and interrelations and from stratigraphic evidence (Reger and Pinney, 1996). We commonly disagree with Karlstrom's (1964) interpretations of the ages and sources of various moraines, particularly in areas such as the northeastern Kenai Lowland, where landforms are

complex and till source is questionable. To test the validity of our model and develop a better understanding of the Naptowne glaciation, we collected 109 till samples and 92 collections of till pebbles to provide sedimentologic evidence that is independent of the evidence on which our model was developed. We reasoned that the compositions of the fine fractions and pebbles of the till samples reflect rock types in the source areas of the glaciers that deposited the tills.

METHODOLOGY

During till sampling, great care was taken to collect only those samples that are not modified by running or standing water. Thus, we generally bagged basal tills and not ablation tills, and we tried to collect both matrix material and pebbles at each sample site, although this was possible at only 85 localities (table 1). Bag samples of till matrix were first sieved into six size fractions, and then, after weighing, we measured the total isotropic magnetic susceptibility of each size fraction. Work by Vonder Haar and Johnson (1973) and Gravenor and Stupavsky (1974) demonstrated that isotropic magnetic susceptibility, which is a function of the amount of ferromagnetic minerals (generally magnetite) in the sample, is useful for classifying and correlating tills. Chernicoff (1984) used isotropic magnetic susceptibility to establish the provenance of two tills in Minnesota. Our till-matrix experiment is based on the premise that isotropic magnetic susceptibility provides a reliable indirect measure of bedrock types in the source areas of the tills in the Cook Inlet trough.

Weights of magnetic-susceptibility samples were measured on a Mettler Electronic Scale, model PE-200, which has a capacity of 0.01 to 120 gm. Initially, three readings of the total magnetic susceptibility were made of each matrix sample by using a Bartington Instruments Magnetic Susceptibility Meter, model M.S. 2, and a Bartington Instruments Sensor, type M.S. 2B, which has a dual frequency. These readings were taken on the low-frequency setting, which provides readings in CGS units and has a scale factor of 0.1. Next, the means of the three initial readings were calculated. Because values measured by the instrument vary with the volume of the sample (which controls the number of ferromagnetic mineral grains present) and not all samples had the same volumes, we standardized mean magnetic-susceptibility readings to absolute units per gram of sample (table 15).

Pebble collections were initially washed and then each pebble was broken to expose a fresh surface. The lithology of each pebble was assigned to one of four general categories (table 16). We propose that the lithology of till pebbles provides a second reliable indicator of bedrock types in till-source areas.

On the basis of its location, each sample was initially

assigned by the proposed model to a particular source area. Most samples from the Talkeetna Mountains, Matanuska Valley, Chugach Mountains, Turnagain Arm, and Kenai Mountains were considered to be unambiguous because they were collected from moraines clearly related to these areas. However, only 23 of 48 till-matrix samples (48 percent) and 18 of 45 pebbles collections (40 percent) were clearly derived from the west side of Cook Inlet. For simplicity, in the glaciation model to be tested the majority of samples that were collected in Kenai Lowland outside of moraines obviously related to the west side of Cook Inlet and to the Turnagain Arm and Skilak Lake lobes (sheet 2 and table 1) were arbitrarily and questionably assigned to the west side of Cook Inlet. Samples of uncertain affinity were also collected from the "interlobate area" of the Matanuska-Knik lobe (Reger and Updike, 1983a), and other ambiguous samples were questionably assigned to Turnagain Arm and Kenai Mountains.

INITIAL RESULTS AND ANALYSIS

Our analysis began with a calculation of mean values and standard deviations for the collections of samples from each source area (tables 17 and 18). Next, simple plots were made to relate the magnetic susceptibilities of till-matrix collections representing the six unambiguous source areas. Among these collections, mean magnetic susceptibilities clearly differentiate three groups of sources: (a) west side of Cook Inlet, (b) Talkeetna Mountains-Matanuska Valley, and (c) Chugach Mountains-Turnagain Arm-Kenai Mountains (fig. 14). Mean magnetic susceptibilities are relatively high in tills that are clearly derived from the west side of Cook Inlet, which is underlain by late Mesozoic and Cenozoic plutonic and associated volcanic, metasedimentary, and sedimentary rocks, including coal-bearing rocks of the Cook Inlet trough (Barnes, 1966; Magoon and others, 1976; Reed and others, 1983). Intermediate mean magnetic susceptibilities characterize till collections from the Talkeetna Mountains and Matanuska Valley. These terranes are dominated by Mesozoic and Cenozoic plutonic and metamorphic rocks of the Talkeetna batholith and associated sedimentary and volcanic rocks of Cenozoic age, including coal-bearing rocks of the Wishbone Hill coal district, as well as rocks from the slightly metamorphosed Mesozoic melange and flysch terranes of the northern Chugach Mountains (Ray, 1954; Barnes and Payne, 1956; Barnes, 1962; Magoon and others, 1976; Winkler, 1992). Mean magnetic susceptibilities are relatively low in tills that are clearly derived from Mesozoic terranes dominated by slightly metamorphosed melange and flysch sequences in the Chugach Mountains, Turnagain Arm, and Kenai Mountains (Martin and others, 1915; Barnes and Cobb, 1959; Clark, 1973; Magoon and others, 1976; Winkler, 1992). On the basis of (*Text cont'd. p. 63*)

^aIncludes sedimentary and altered sedimentary lithologies.

standard deviations of mean magnetic susceptibility, the collection of samples from the west side of Cook Inlet is clearly more variable than the other collections, but collections from Talkeetna Mountains, Kenai Mountains, and Matanuska Valley have intermediate standard deviations in the finer size fractions (fig. 15).

These preliminary results persuaded us that our experiment could produce useful information on till sources. We reasoned that multivariate analysis, which can incorporate both magnetic-susceptibility and pebble-lithology values, could provide statistically significant results.

RESULTS OF MULTIVARIATE ANALYSIS

The goal of the multivariate analysis was to develop an appropriate numerical scheme to accurately predict sources of tills in the eastern and northern Cook Inlet region. Our data set consists of 10 independent variables (magnetic-susceptibility readings of six size fractions of till matrix plus four compositional classes of till pebbles) and six dependent variables (the source areas identified in the model). Three multivariate programs were used in this evaluation: (a) CHAID, which detects data interactions by the use of decision trees; (b) multiple discriminant

Figure 15. Standard deviation of mean magnetic susceptibility of six size fractions in 68 till samples from six known source areas in the Cook Inlet region.

analysis (MDA); and (c) AIM (abductive inference mechanism). Details of these analyses are provided in appendix B.

Predictions of till sources by the proposed model were significantly matched by CHAID predictions at both the 99- and 95-percent levels, which provides important confirmation of the proposed glaciation model (figs. 16 and 17). However, the location and nature of CHAID mismatches also provide important insights about the Naptowne glaciation in the Cook Inlet trough. A small number of samples collected in the eastcentral and southeastern Cook Inlet trough from moraines clearly related to ice from the Kenai Mountains was erroneously assigned (primarily at the 95-percent confidence level) to Turnagain Arm, which served as a major conduit for ice from virtually identical bedrock terranes in the northern Kenai Mountains and southern Chugach Mountains. At both

confidence levels, almost all mismatches occurred at sample sites where there is least confidence in the proposed glaciation model, namely in northern Kenai Lowland and in the interlobate belt associated with the Matanuska-Knik lobe north of Anchorage. In northern Kenai Lowland, samples assigned by the model to west side sources were assigned by CHAID to the Chugach Mountains, Kenai Mountains, or Matanuska Valley. Disparities among "interlobate" samples were assigned by CHAID to the Kenai Mountains, which is clearly not possible.

CHAID was also used to analyze the relative significance of the four lithologies in the pebble classification. Metasediment content was judged the only significant indicator among the four lithologic classes. However, limiting CHAID only to pebble lithology greatly blunted the sensitivity of the technique. CHAID chose magnetic susceptibility of the 1- ϕ (coarse-sand) fraction

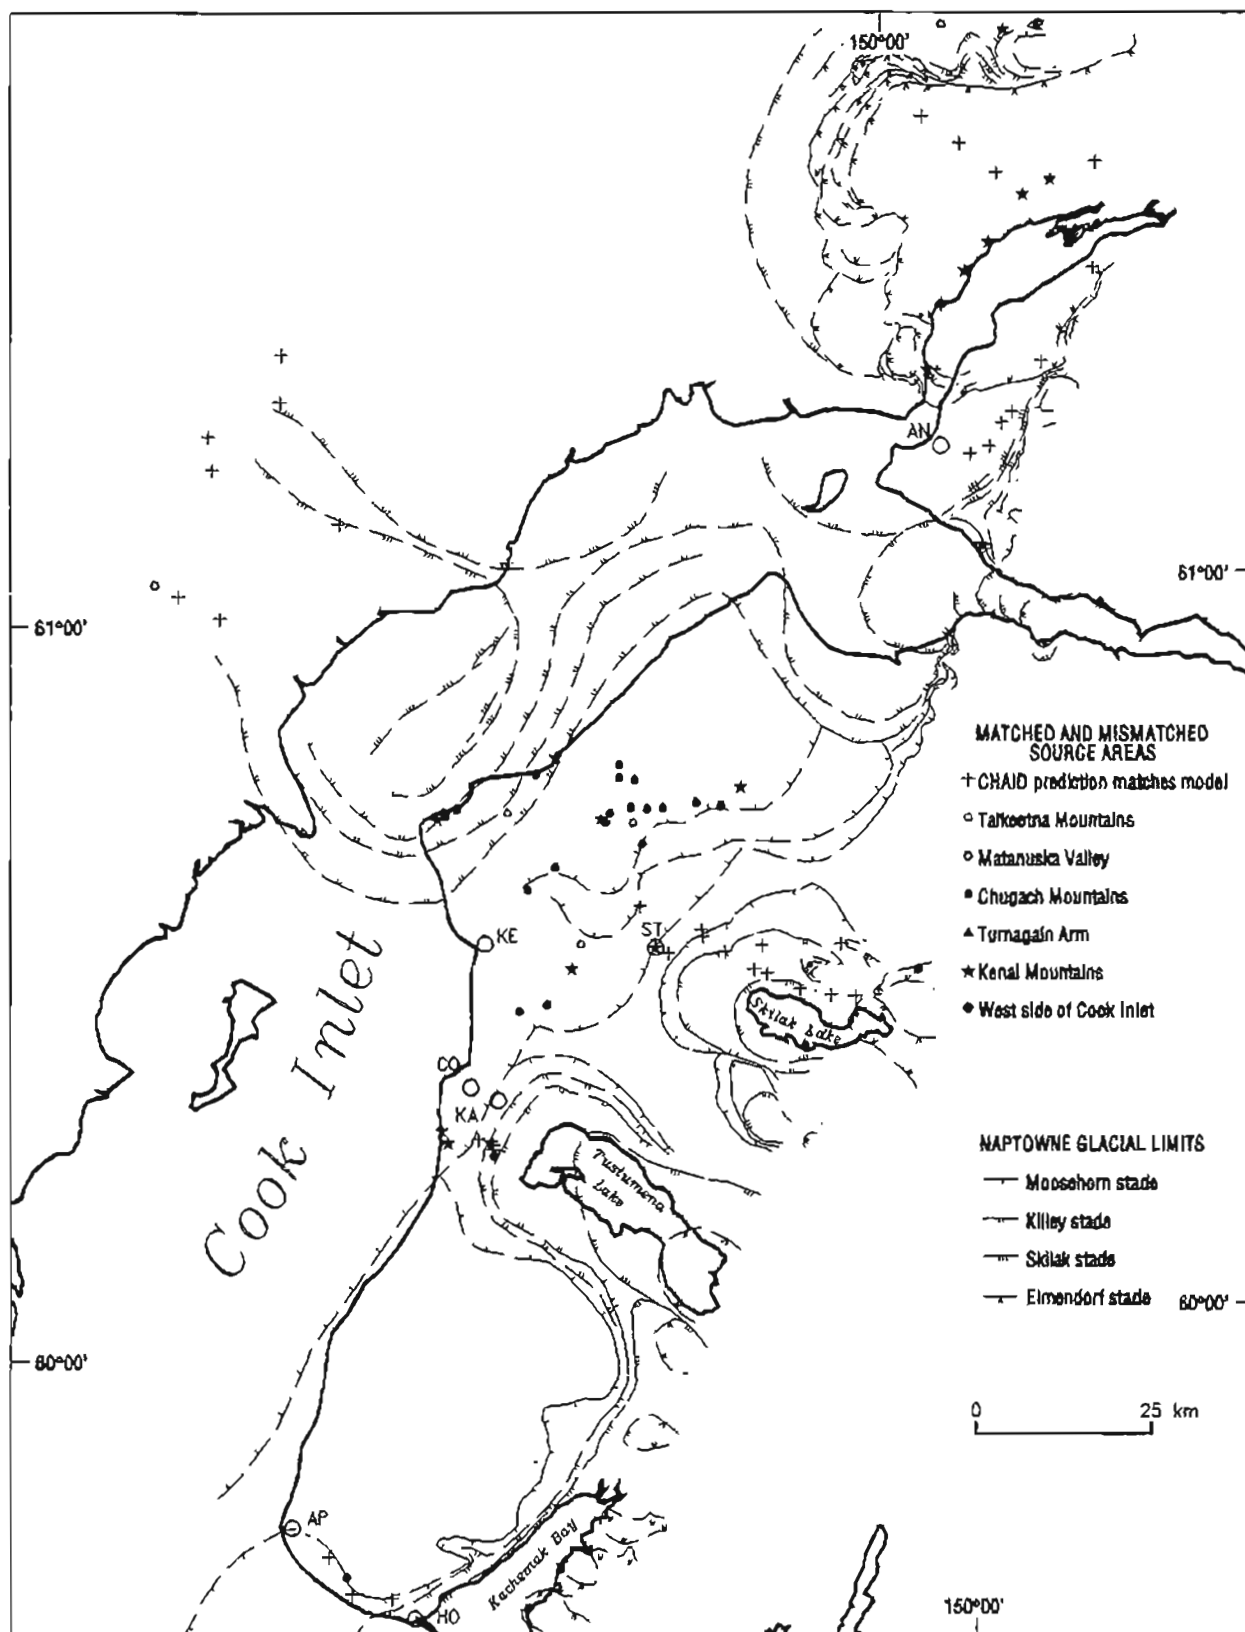

Figure 16. Comparison of CHAID predictions at the 99-percent confidence level and till sources predicted by the proposed glaciation model in the Cook Inlet region. Geographic localities: AN = Anchorage; AP = Anchor Point; CO = Cohoe; HO = Homer; KA = Kasilof; KE = Kenai; ST = Sterling.

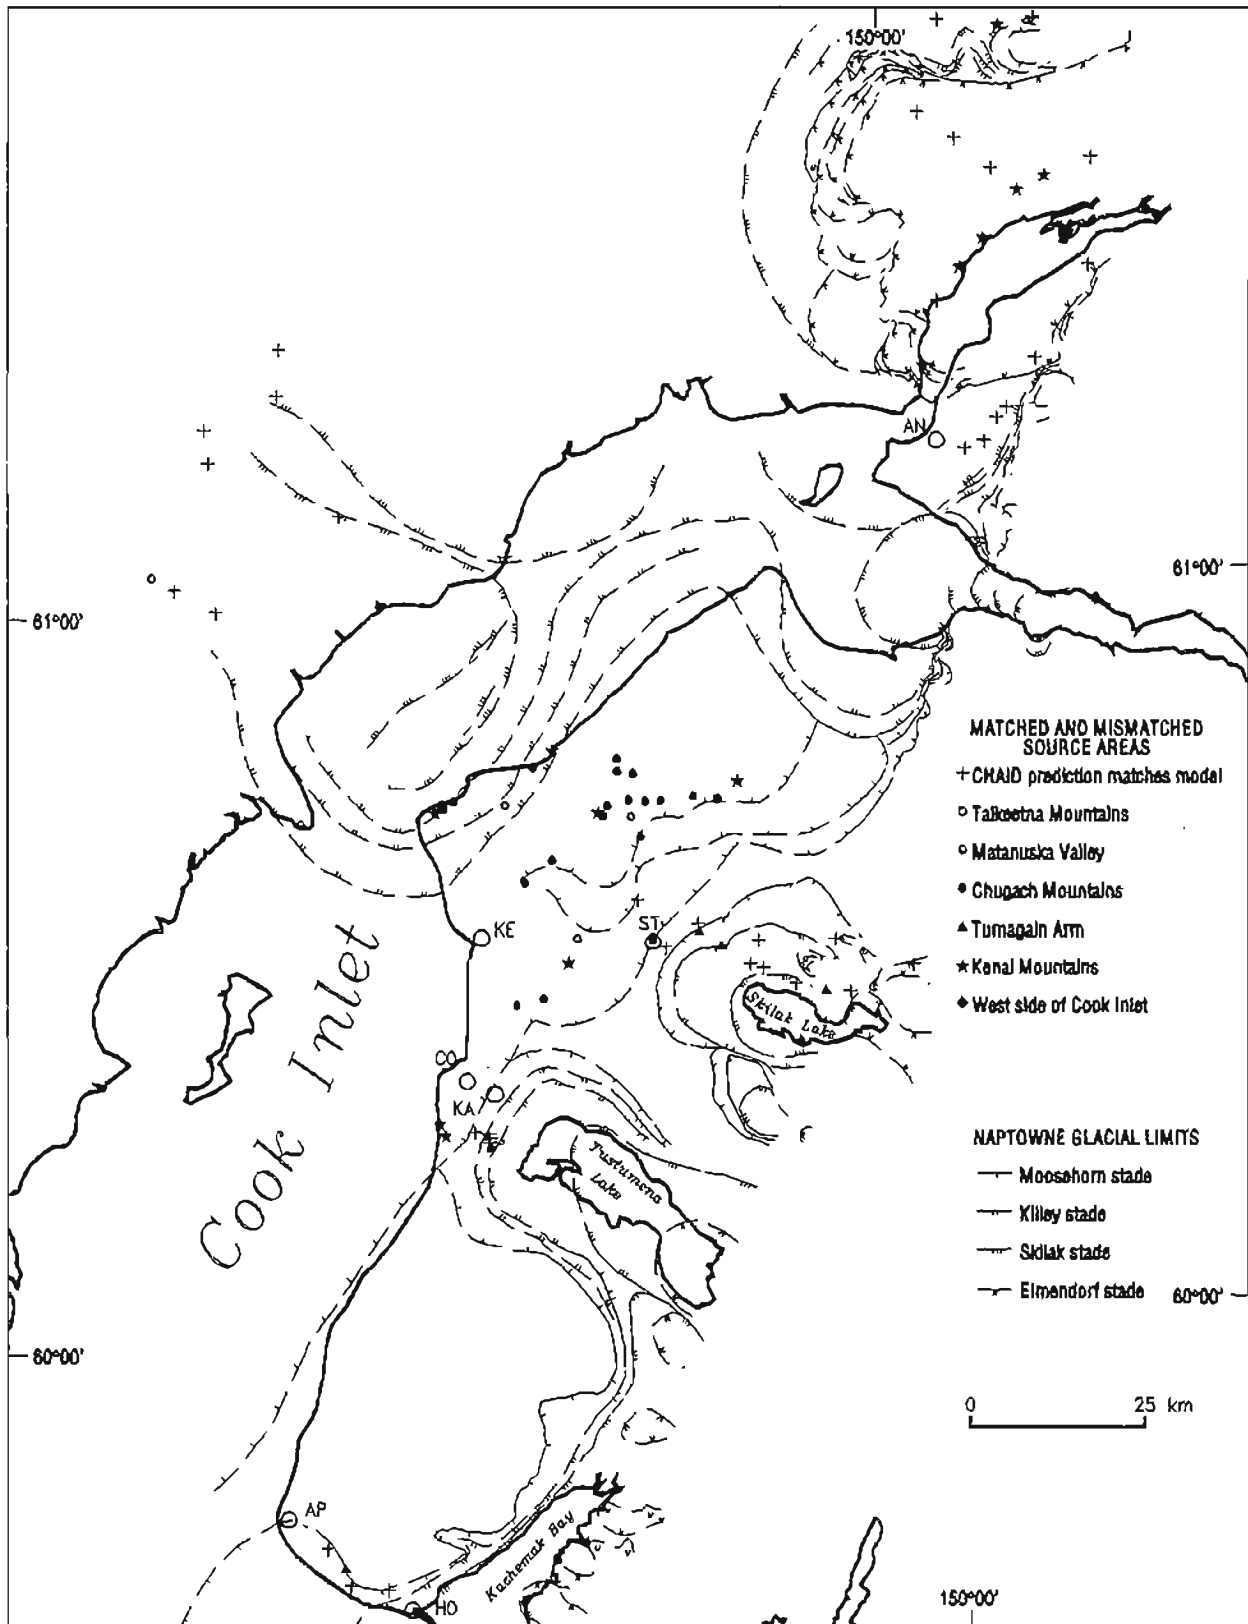

Figure 17. Comparison of CHAID predictions at the 95-percent confidence level and till sources predicted by the proposed glaciation model in the Cook Inlet region. Geographic localities: AN = Anchorage; AP = Anchor Point; CO = Cohoe; HO = Homer; KA = Kasilof; KE = Kenai; ST = Sterling.

and 4- ϕ (very fine sand) fraction of the till matrix and contents of metasediment and plutonic pebbles as significant predictors of till source in this study.

Although the basic requirements of MDA were not satisfied by our data set because of its limited size, MDA clearly indicates that percentages of metasediment and plutonic lithologies in till pebble collections are significant indicators of till sources in the eastern and northern Cook Inlet trough. Many model predictions were confirmed by MDA, which produced only a few more mismatches (fig. 18) than did CHAID. Mismatches in Skilak Lake, Tustumena Lake, and Kachemak Bay samples result from MDA assignments (in decreasing order) to Turnagain Arm, Chugach Mountains, and Matanuska Valley. Mismatches of granitic-rich and locally derived till samples from the west side of Cook Inlet resulted from MDA assignments to the Talkeetna Mountains, which are cored by the extensive Talkeetna batholith. As with CHAID, most MDA mismatches are concentrated in northern Kenai Lowland, where model predictions are shakiest. There, tills attributed

to the west side of Cook Inlet by the glacial model were assigned about equally by MDA to Matanuska Valley and Chugach Mountains.

AIM could not successfully partition our data set. However, it determined (although not conclusively) that three factors are significant for differentiating till sources in the eastern and northern Cook Inlet trough: (a) magnetic susceptibility of the 4- ϕ (very fine sand) fraction, (b) percentage of metasediment pebbles, and (c) percentage of plutonic pebbles.

IMPLICATIONS

Multivariate analysis successfully partitioned our data set to identify the six till sources predicted by the glaciation model. However, the data set probably provides indicative and not conclusive results because it is too small to comprehensively represent the complex glacial deposits in the Cook Inlet trough. Nonetheless, the three approaches tested produce mutually supportive results. Disparities

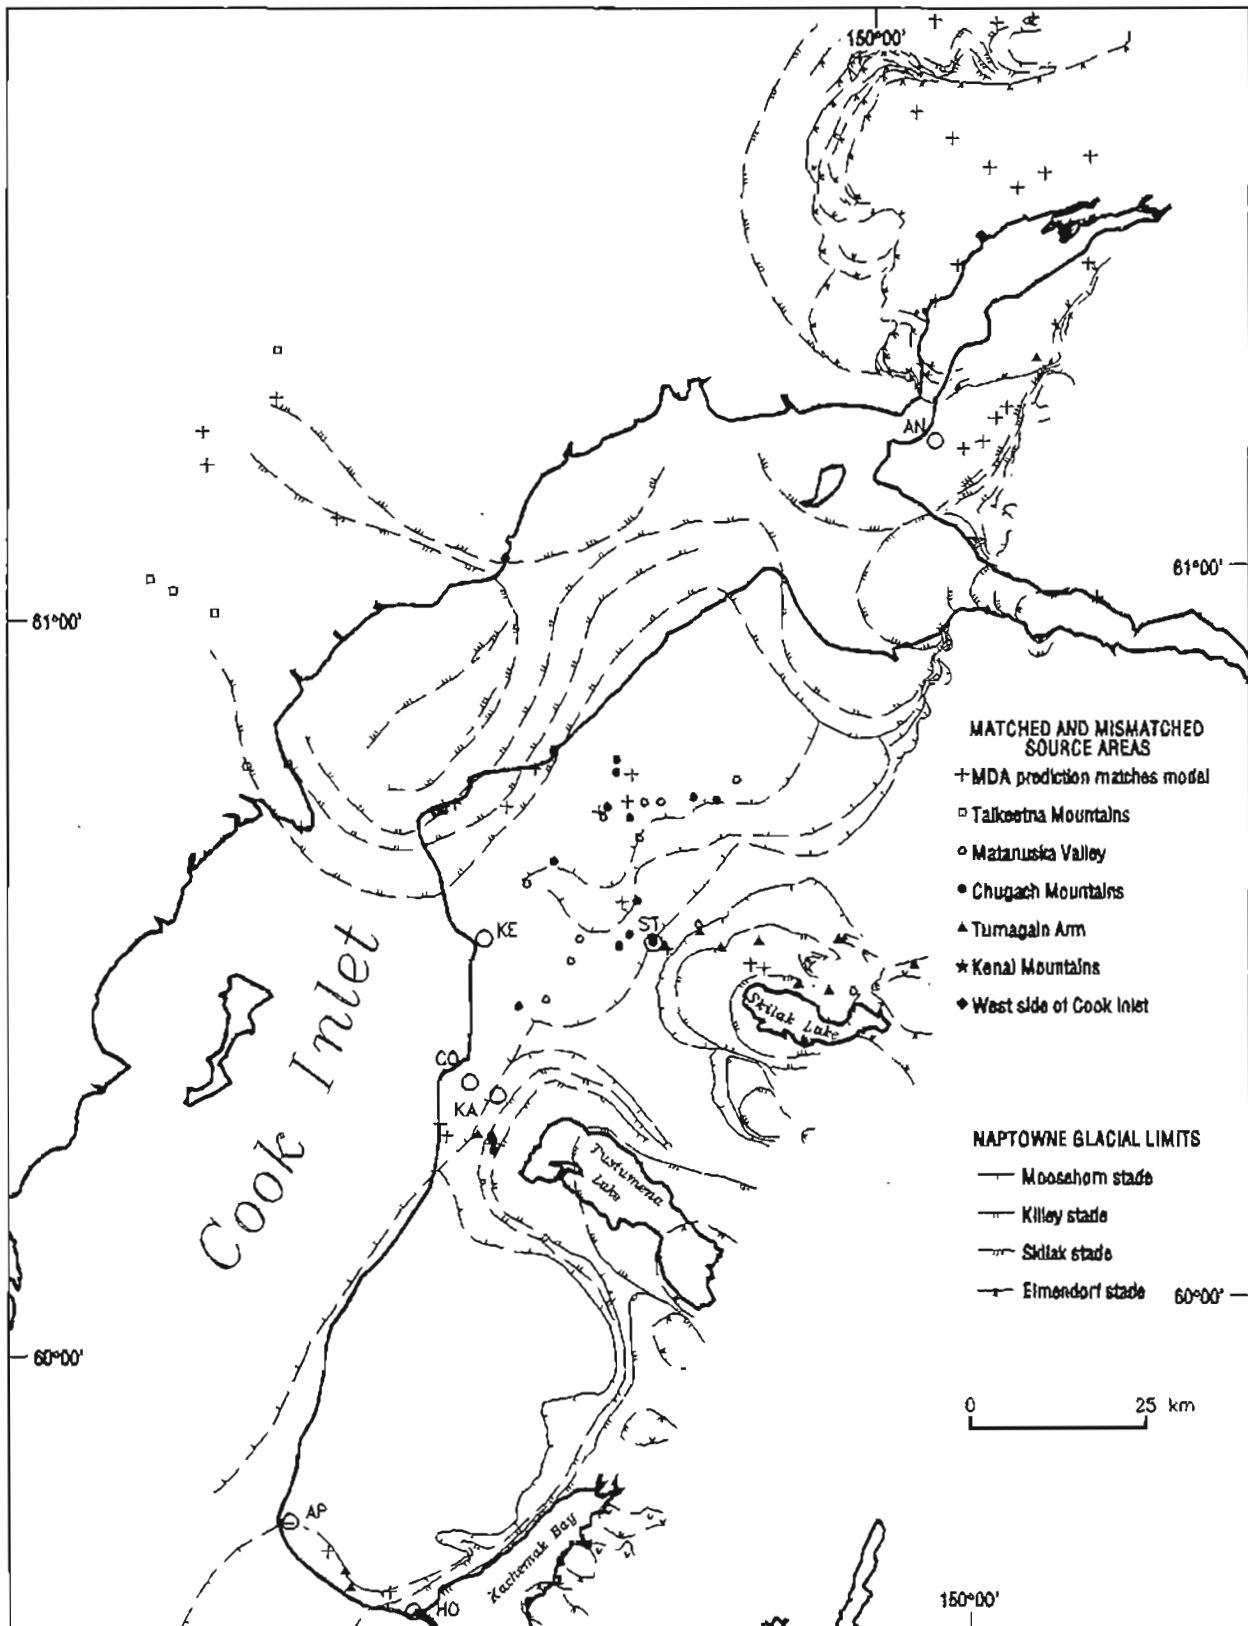

Figure 18. Comparison of till sources predicted by multiple discriminant analysis and sources predicted by the proposed glaciation model in the Cook Inlet region. Geographic localities: AN = Anchorage; AP = Anchor Point; CO = Cohoe; HO = Homer; KA = Kasilof; KE = Kenai; ST = Sterling.

between model predictions and predictions by CHAID and MDA are generally related to lack of confidence in model assignments.

Differences in the proposed glaciation model and statistical predictions in "known" moraines are probably due to the inability of CHAID and MDA to distinguish between subtle differences of bedrock in different source areas based on this data set. Concentrations of mismatches probably indicate that ice of Naptowne age entered northern Kenai Lowland not just from the northwest but also from the north and northeast (fig. 19), similar to the glacioestuarine model proposed by Schmoll and others (1984, fig. 7). However, based on near-surface stratigraphy and landform interrelations in Kenai Lowland, we have a different interpretation than them for the nature, extent, and age of former waterbodies in the Cook Inlet trough (Reger and Pinney, 1996). Complications for an interpretation of statistical mismatches in northern Kenai Lowland include (a) scouring and incorporation of weakly cemented Tertiary bedrock (particularly on the west side of Cook Inlet) and (b) probable reworking during the Naptowne advance of older Pleistocene deposits, perhaps from more than one source.

On the basis of our pilot study, we suggest that a final resolution of a model of Naptowne glaciation in the Cook Inlet trough should include a consideration of the results of multivariate analysis of a data set produced by an expanded and more intensive till sampling program. Initial results indicate that this program can be limited to measuring the isotropic magnetic susceptibility of the coarse-sand and very fine sand fractions of the till matrix and to determining the percentages of metasediment and plutonic till pebbles. Results of this statistical approach should be compatible with landform interrelations and stratigraphy.

CONCLUSIONS

The most widespread and chronologically most important tephra we document in Kenai Lowland is the Lethe tephra, which is the key to correlating morainal sequences from Kachemak Bay to Turnagain Arm (Reger and Pinney, 1996). This dacitic airfall tephra strongly correlates with complex pyroclastics in the the Windy Creek area near Mt. Katmai, based on ferromagnesian mineral content, distinctive shard morphology, and very consistent shard geochemistry. Stratigraphic and physiographic evidence in Kenai Lowland indicates that the Lethe tephra was deposited after 16,000 ^{14}C yr B.P. late in the Killey stage of the Naptowne glaciation.

We recognize nine Holocene tephras and tentatively recognize four tephras in Kenai Lowland. On the basis of shard geochemistry, we tentatively suggest that several of these tephras could have been erupted from Mt. Augustine, Mt. Redoubt, and Hayes volcano on the west side of Cook Inlet.

However, the Crooked Creek and Funny River tephras, which are best represented among the Holocene tephras in our sampling program, have no known correlatives.

Our investigations of the regionally important section at Goose Bay on the west side of Knik Arm indicate that the Goose Bay peat, its enclosed tephras, and the underlying type till of the Knik glaciation are middle Pleistocene in age. In several attempts to date the Goose Bay tephra, which is the thickest volcanic ash in the section, we conclude that the best result is a three-sample (composite) isochron $^{40}\text{Ar}/^{39}\text{Ar}$ age of 378 ± 0.67 ka, obtained by the laser method. We also confirm the presence of the Stampede tephra, previously identified by Begét and Keskinen (1991), at the base of the Goose Bay peat.

Evidence in the bluff at Kenai demonstrates that a tide-water glacier floated there late in the Killey stage shortly after $16,480 \pm 170$ ^{14}C yr B.P. and that a marine connection existed between middle Cook Inlet and the North Pacific Ocean. Stratigraphic and paleontologic evidence in the Kasilof-Kalifornsky area indicates that inlet waters were very cold with variable turbidity and salinity about 16,000 ^{14}C yr B.P. and that debris-laden icebergs were present.

Macrofossil collections from the Bootlegger Cove Formation in upper Cook Inlet are dominated by pelecypods with minor gastropod and barnacle components. These assemblages are rich in species compared to the modern *Macoma balthica* fauna. Between $14,900 \pm 400$ and $13,470 \pm 120$ ^{14}C yr B.P., BCF faunas probably lived in conditions that were very similar to some modern fjords along the southcentral and southeastern coast of Alaska, except there was strong tidal action.

Our pedologic observations raise serious questions about past practices of correlating moraines by similar soil development. We conclude that significant environmental gradients in the Cook Inlet region probably affected rates of soil formation and seriously complicate the use of soils to date landforms.

Multivariate analysis of six size fractions of till matrix and four compositional classes of till pebbles was successfully used to test a model of Naptowne glaciation in the eastern and northern Cook Inlet region. Concentrations of discrepancies between model and statistical predictions probably indicate that Naptowne ice entered the northern Kenai Lowland from the northwest, north, and northeast.

ACKNOWLEDGMENTS

We gratefully acknowledge the critical contributions made by many of our colleagues during field and laboratory phases of this investigation. Able assistance was provided in the field by Rod Combellick, Cheri Daniels, Jeff Kline, Sven Lagerberg, Bill Petrik, Doug Reger, and Fred Sturmman. On numerous occasions, we depended on

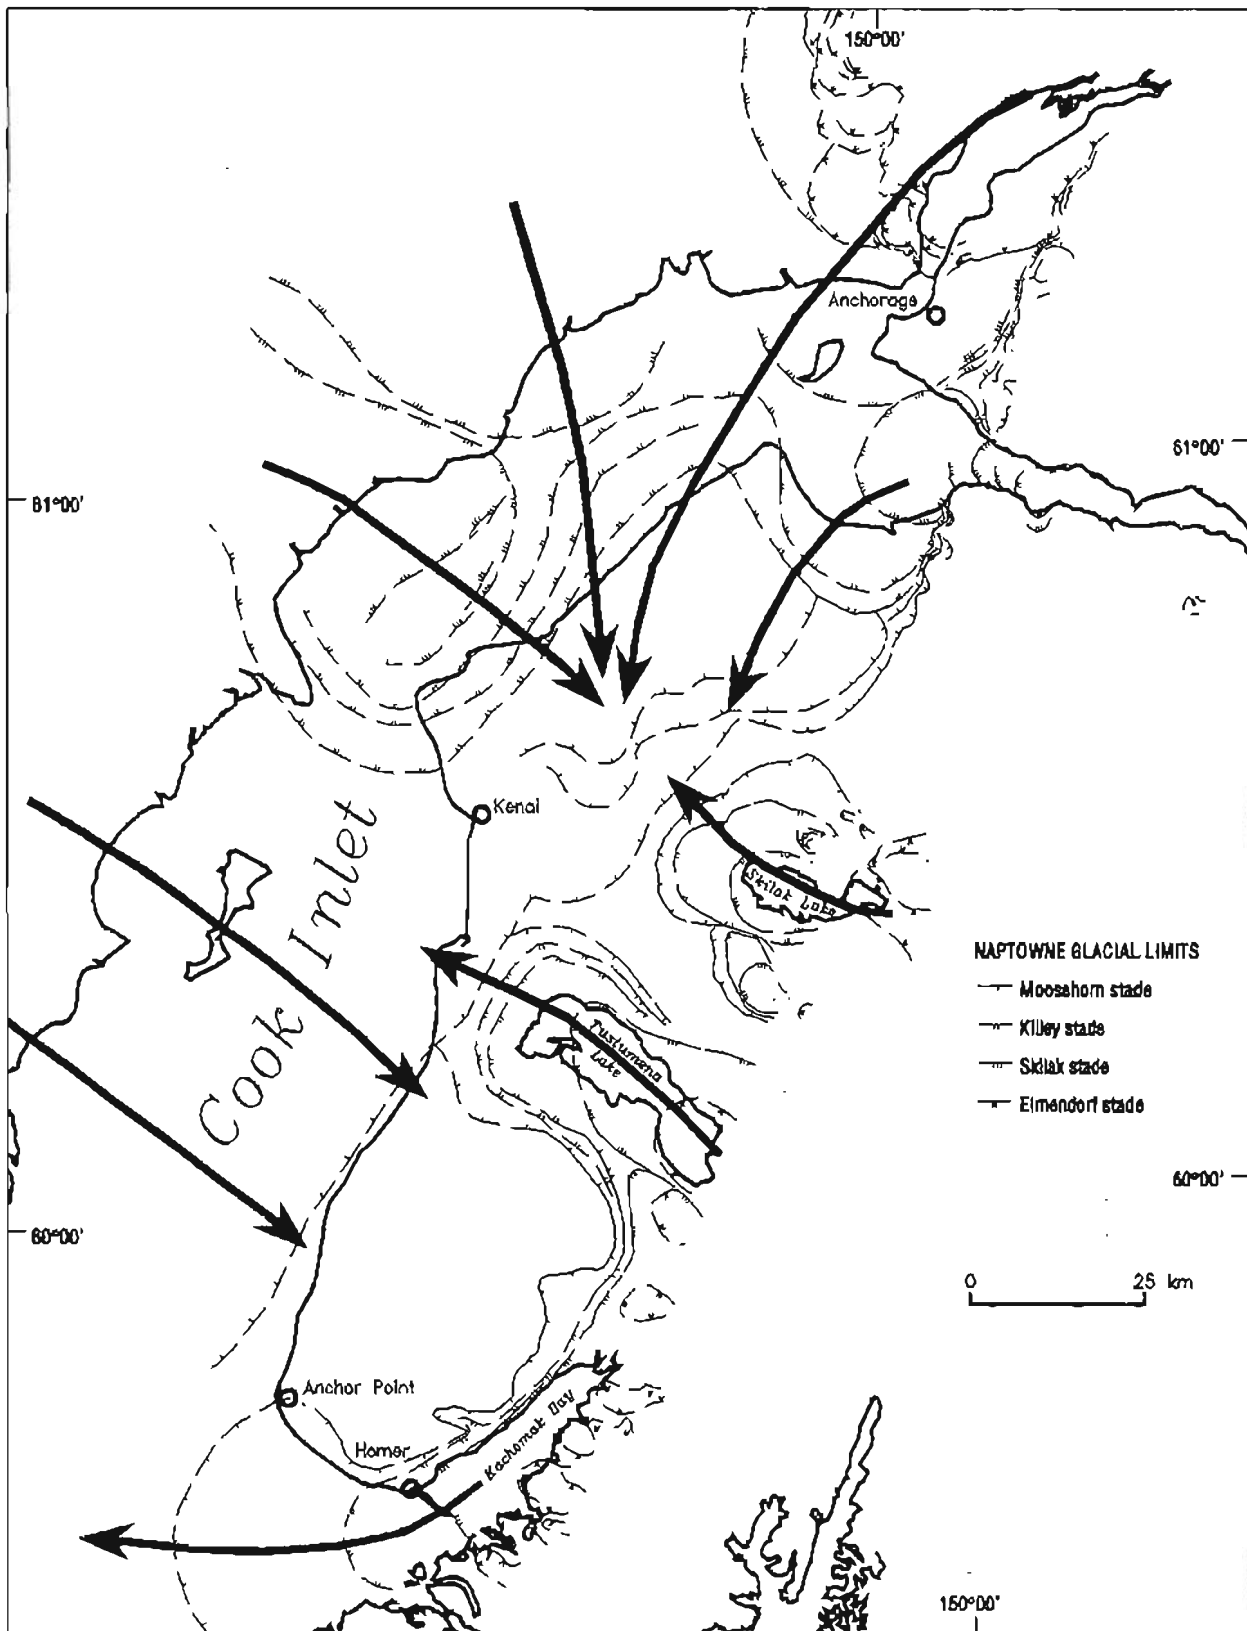

Figure 19. Revised model of Naptowne glaciation in the Cook Inlet region, showing major ice-flow directions (arrows) inferred from multivariate analysis of magnetic-susceptibility and pebble compositions of till samples.

the expert advice and outstanding cartographic products provided by Sturmann. We appreciate permission to map and sample the Kenai National Moose Range by Dan Doshier, U.S. Fish and Wildlife Service.

Several folks helped analyze the many samples we collected during the past 19 years. We are particularly appreciative of the friendly hospitality and technical support provided by Scott Cornelius and Diane Johnson, who expertly program and maintain the electron microprobe in the Washington State University Geochronology Laboratory. Preliminary correlations of Holocene tephra in the Cook Inlet region were facilitated by our access to unpublished geochemical data that were kindly provided to Pinney by Jim Begét, Kathy Campbell, Tom Dilley, Sam Swanson, and Victoria Avery. Dr. Paul Layer, University of Alaska (Fairbanks) Geochronology Laboratory, kindly analyzed tephra samples that ultimately provided the important $^{40}\text{Ar}/^{39}\text{Ar}$ date of the Goose Bay tephra. Dr. Bob Zimmerman, U.S. Geological Survey, searched thousands of apatite grains in the Goose Bay tephra for fission tracks and ultimately provided a mean fission-track age for that tephra. Our radiocarbon samples were analyzed by the University of Arizona (AA); Beta Analytic, Inc. (Beta); Teledyne Isotopes (I); Geochron Laboratories (GX), Washington State University Radiocarbon Dating Laboratory (WSU), and University of Washington Quaternary Isotope Laboratory (QL). John Roe measured the paleomagnetism of our Goose Bay samples with the permission of Dr. David Stone, University of Alaska (Fairbanks) Geophysical Institute. Nora Foster, University of Alaska (Fairbanks) Museum, efficiently identified the constituents of our macrofossil collections from the Bootlegger Cove Formation. Our collections of microfossils from the Bootlegger Cove Formation were inventoried by Micropaleo Consultants, Inc. We are grateful to Al Kimker, Alaska Department of Fish and Game, for discussions on the distributions and habitat requirements of modern pelecypods in Cook Inlet.

We thank Dr. Tom Ager, U.S. Geological Survey, for letting us use the unpublished radiocarbon date from the bottom of his Circle Lake core.

A special tip of our hats goes to Dr. Dan Hawkins, geostatistician extraordinaire now enjoying a busy retirement from the University of Alaska (Fairbanks). Dan became intrigued by the the potential of using a combination of magnetic susceptibility and pebble contents in till samples to identify till sources. He efficiently ran our data through their statistical paces and, in the process, segregated key parameters for six source areas. In addition to his obvious technical expertise and review of appendix B, we are grateful for Dan's enthusiastic support and patience in answering many questions asked by these statistical neophytes.

We are thankful for technical reviews of this report

by Dr. Troy Péwé, Department of Geology, Arizona State University; Kristine Crossen, Department of Geology, University of Alaska (Anchorage); and Karen Clautice, DGGs. We especially hope that Kris will pursue similar studies in the Cook Inlet region in the future. And last, but not least by any measure, we give well-earned credit to Fran Tannian, who patiently and efficiently answered our many editorial questions, and to Frank Larson, whose editing skills and attention to detail helped us find elusive typos, clarify awkward sentences, and apply the final polish to this report.

APPENDIX A

Stratigraphic sections and soil profiles associated with middle to late Pleistocene deposits in the Cook Inlet region. Observation dates are shown at the top of the sections. Stratigraphic symbols and terminology are defined in table A.1. Soil-profile terminology is defined in table A.2. Geochemistry of glass shards in tephra with asterisk (*) numbers was analyzed by electron microprobe but is not reported because of great variation. Question mark after tephra number indicates that tephra designation is very tentative due to small number of shards segregated. Tephra without numbers were not sampled.

Table 1A. Symbols and terminology used in stratigraphic sections

	Organic material or peat		Loess (eolian silt)
	Clay		Tephra
	Silt		Silt and clay rhythmite
	Sand		Sand and silt rhythmite
	Pebble gravel		Blocky rubble
	Diamiction, mixed coarse and fine material		Invertebrate fossil sample
	Wood		Microfossil sample
	Dropstone		Fission-track sample
	Radiocarbon sample		Sand wedge
	$^{39}\text{Ar}/^{40}\text{Ar}$ sample		

Estimated content of silt, sand, and gravel is based on field observations and general composition in summary descriptions of stratigraphic sections as indicated by nonquantitative terms:

Some = 12 to 30 percent

Trace = 4 to 12 percent

Not recorded <4 percent

Estimated content of cobbles and boulders is based on field observations and general composition in summary descriptions of stratigraphic sections as indicated by nonquantitative terms:

Numerous = two cobbles or boulders in 0.6 m section

Scattered = two cobbles or boulders in 3 to 4.5 m section

Rare = two cobbles or boulders in section >4.5 m

Table A2. Definitions of symbols in summary soil descriptions (Soil Survey Staff, 1975; modified by Harden, 1982; Birkeland, 1984; Birkeland and others, 1991b; and this study)

Characteristic	Symbol	Definition	Measure
Structure	l	Few present	Few/dm ³
	m	Massive	No peds developed
	sg	Single grained	No particle bonding
	vl	Very weak	Very few, indistinct peds
	f	Fine or thin	Plates 1-2 mm, blocks 5-10 mm
	pl	Platy	Particles oriented in horizontal planes
	sbk	Subangular blocks	Peds faces round and planar
Consistence	lo	Loose (dry and moist)	Noncoherent
	so	Weakly coherent (dry)	Powders easily
	so	Nonsticky (wet)	No adherence
	ss	Slightly sticky (wet)	Slight adherence, stretches
	po	Nonplastic (wet)	No rod forms
	ps	Slightly plastic (wet)	Weak rod forms
Roots	v)	Very few present	Very few/dm ³
	1	Few present	Few/dm ³
	2	Commonly present	Common/dm ³
	3	Many present	Many/dm ³
	vf	Very fine	<1 mm dia
	f	Fine	1 to 2 mm dia
	m	Medium	2 to 5 mm dia
Pores	co	Coarse	>5 mm dia
	1	Few present	Few/dm ³
	2	Commonly present	Common/dm ³
	3	Many present	Many/dm ³
	vf	Very fine	0.1 to 0.5 mm dia
	f	Fine	0.5 to 2 mm dia
	m	Medium	2 to 5 mm dia
	tub	Tubular shape	Cylindrical, elongate pores
	ves	Vesicular shape	Spherical or elliptical pores
	ir	Irregular shape	Walls of pores curves or angular
Lower boundary	a	Abrupt	Transition w/in 1 mm to 2.5 cm
	c	Clear	Transition w/in 2.5 to 6 cm
	g	Gradual	Transition w/in 6 to 12.5 cm
	d	Diffuse	Transition >12.5 cm
	i	Irregular	Undulates, pocket depths >widths
	s	Smooth	Parallel to ground surface
	w	Wavy	Undulates, pocket depths <widths
	b	Broken	Parts of horizon laterally discontinuous

³Exact number varies with size of structure, root, or pore (Soil Survey Staff, 1975, p. 479-481).

Table A3. Summary field description of soil profile S1 measured 08-14-90 on flat crest of type Killey moraine (60°31'25"N, 150°37'42"W), Kenai C-2 SW Quadrangle (KEN-79, sheet 2). Elevation 101 m. ^aCumelic?

^bMixture of silt and clay form caps on pebbles. Coatings are moderately thick in Bw.

^cVery bright (5YR3/4 (dark reddish brown)) stone coatings.

^dSlightly mottled.

Vegetation: Alpine meadow of crowberry (*Empetrum nigrum*) mat with scattered cloudberry (*Rubus chamaemorus*), grasses (*Calamagrostis* sp.), spirea (*Spirea Beauverdiana*) shrubs, lingonberry (*Vaccinium vitis-idaea*), and tall fireweed (*Epilobium angustifolium*).

Figure A1. Stratigraphy exposed in section 1 (61°50'05"N, 149°58'39"W), Anchorage D-8 SW Quadrangle (ANC-1, sheet 1). Chronologic significance of radiocarbon date given in table 2.

Figure A2. Stratigraphy exposed in section 2 (61°41'44"N, 149°15'05"W), Anchorage C-7 NE Quadrangle (ANC-9, sheet 1). Chronologic significance of radiocarbon date given in table 2.

Figure A4. Stratigraphy exposed in section 4 (61°15'34"N, 149°55'57"W), Anchorage B-8 SW Quadrangle (ANC-36, sheet 1). Chronologic significance of radiocarbon date given in table 2.

Figure A5. Stratigraphy exposed in section S (61°14'17"N, 149°58'57"W), Anchorage A-8 NW Quadrangle (ANC-39, sheet 1). Chronologic significance of radiocarbon date given in table 2.

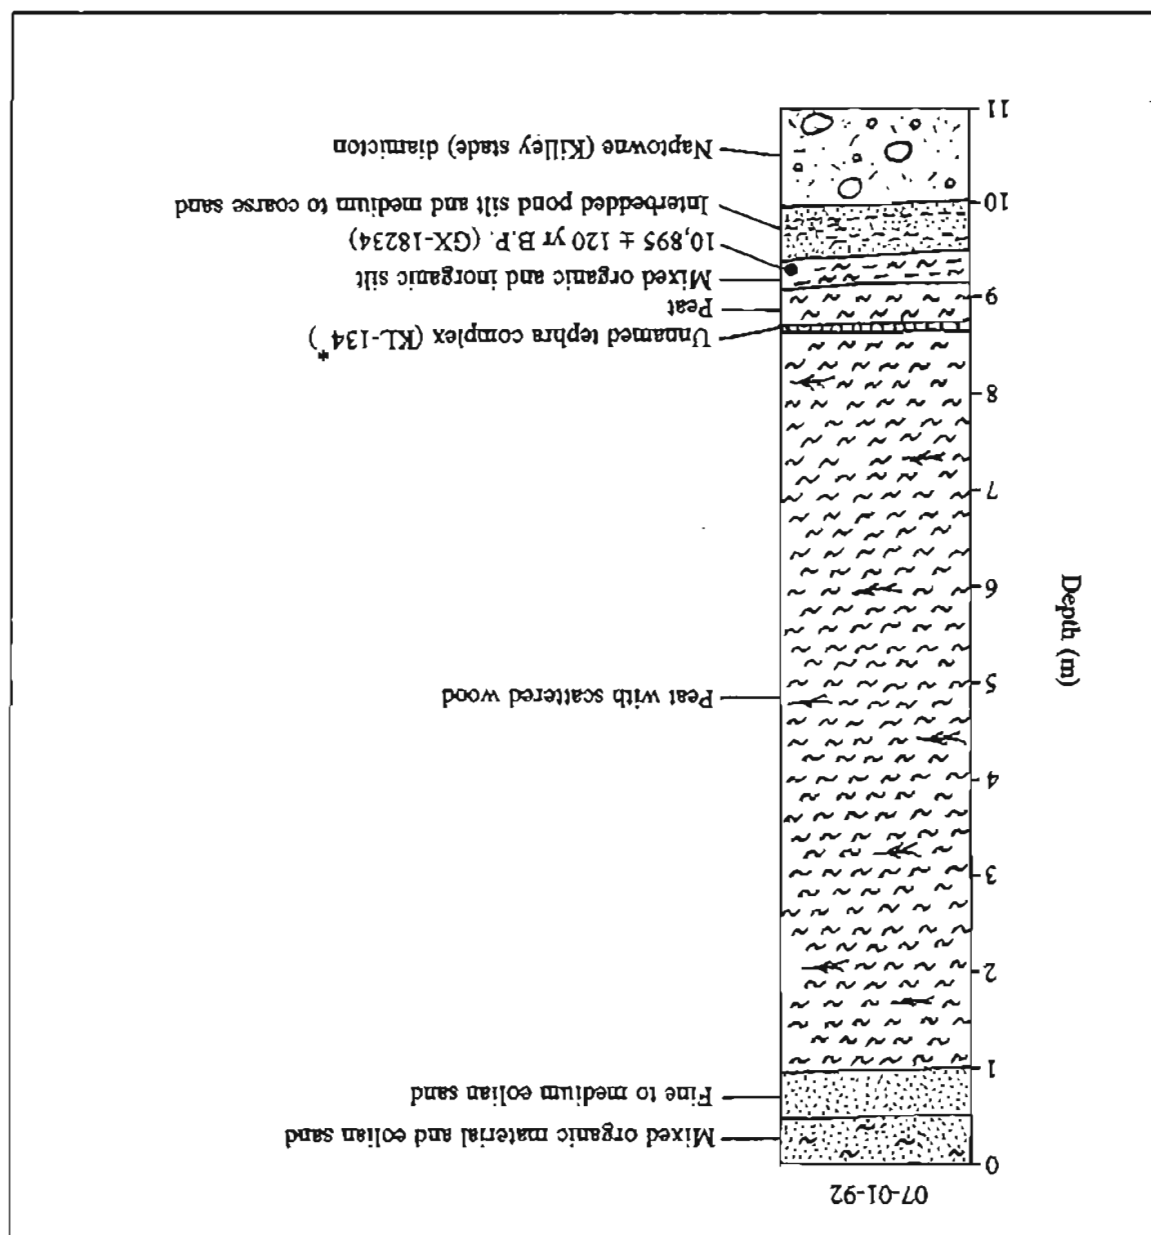

Figure A6. Stratigraphy exposed in section 6 (60°58'48"N, 150°18'11"W), Kenai D-1 NW Quadrangle (KEN-1, sheet 2). Chronologic significance of radiocarbon date given in table 2.

Figure A7. Stratigraphy exposed in section 7 (60°58'02"N, 150°17'20"W), Kenai D-1 NW Quadrangle (KEN-2, sheet 2). Chronologic significance of radiocarbon dates given in table 2. Tephra geochemistry given in table 3.

Figure A17. Stratigraphy exposed in section 17 ($60^{\circ}37'25''N$, $151^{\circ}07'54''W$), Kenai C-4 SE Quadrangle (KEN-44, sheet 2). Tephra geochemistry given in table 3. Section indicates Killey age for fan delta near Kenai.

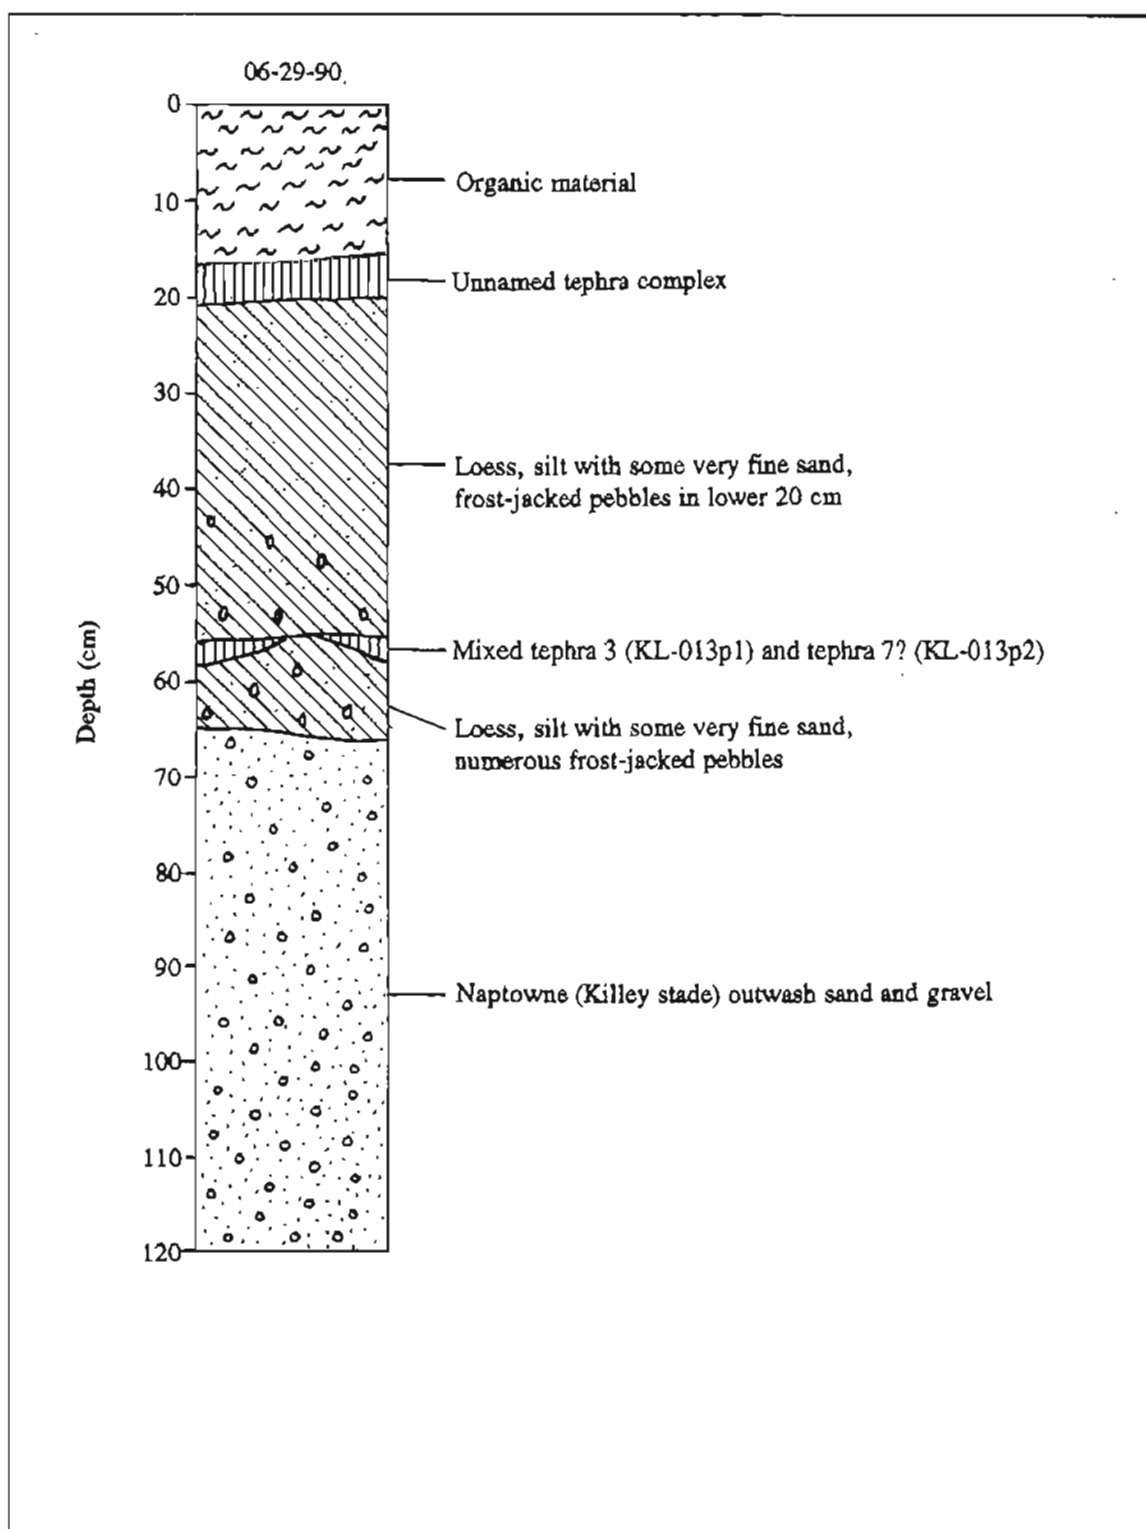

Figure A16. Stratigraphy exposed in section 16 ($60^{\circ}38'05''\text{N}$, $151^{\circ}20'02''\text{W}$), Kenai C-4 NW Quadrangle (KEN-41, sheet 2). Tephra geochemistry given in table 3, except for unnamed tephra complex.

Figure A15. Stratigraphy exposed in section 15 ($60^{\circ}38'17''N$, $151^{\circ}04'22''W$), Kenai C-3 NW Quadrangle (KEN-40, sheet 2). Tephra geochemistry given in table 3. Section indicates Killey age for upper terrace on east side of Beaver Creek and associated paleodrainage system down Swanson River from terminal moraines of Turnagain Arm lobe.

Figure A14. Stratigraphy exposed in section 14 (60°38'58"N, 150°49'21"W), Kenai C-3 NE Quadrangle (KEN-38, sheet 2). Tephra geochemistry given in table 3. Section demonstrates late Killey age for eolian sand in meltwater channels through Moosehorn moraine in finger Lakes area.

Figure A13. Stratigraphy exposed in section 13 (60°39'38"N, 151°18'55"W), Kenai C-4 NW Quadrangle (KEN-36, sheet 2). Tephra geochemistry given in table 3, except for unnamed tephra complex. Section indicates Killey age for outwash in Salamatoof area.

Figure A12. Stratigraphy exposed in section 12 ($60^{\circ}43'25''N$, $151^{\circ}54'15''W$), Kenai C-3 NE Quadrangle (KEN-27, sheet 2). Tephra geochemistry given in table 3. Section indicates Killey age for Swanson River paleodrainage system from moraines of Turnagain Arm lobe to 25-m marine terrace at Kenai.

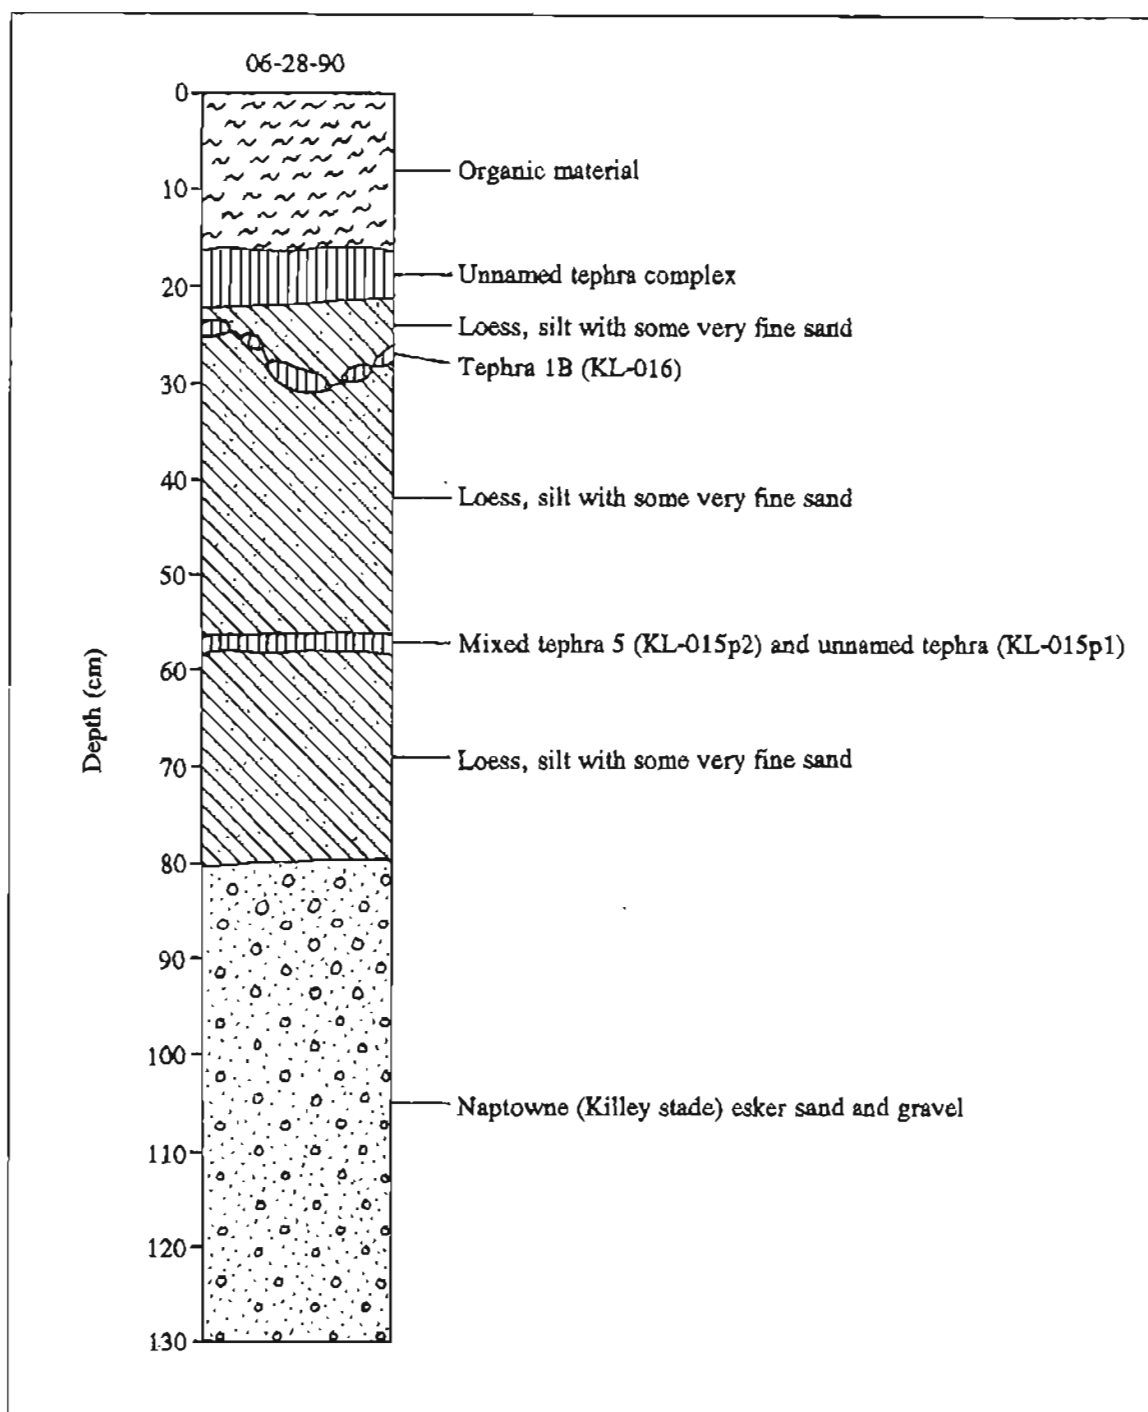

Figure A11. Stratigraphy exposed in section 11 (60°43'59"N, 151°09'37"W), Kenai C-4 NE Quadrangle (KEN-18, sheet 2). Tephra geochemistry given in table 3, except for unnamed tephra complex.

Figure A10. Stratigraphy exposed in section 10 (60°44'27"N, 151°18'07"W), Kenai C-4 NE Quadrangle (KEN-15, sheet 2). Tephra geochemistry given in table 3, except for unnamed tephra complex.

Figure A9. Stratigraphy exposed in section 9 ($60^{\circ}44'58''N$, $150^{\circ}51'27''W$), Kenai D-3 SE Quadrangle (KEN-14, sheet 2). Tephra geochemistry given in table 3.

Figure A8. Stratigraphy exposed in section 8 (60°47'59"N, 151°00'56"W), Kenai D-3 SW Quadrangle (KEN-6, sheet 2).

Figure A18. Stratigraphy exposed in section 18 (60°35'47"N, 151°12'49"W), Kenai C-4 SE Quadrangle (KEN-46, sheet 2). Chronologic significance of radiocarbon dates given in table 2. Tephra geochemistry given in table 3, except for unnamed tephra complexes.

Figure A19. Stratigraphy exposed in section 19 (60°34'24"N, 151°13'46"W), Kenai C-4 SE Quadrangle (KEN-50, sheet 2). Tephra geochemistry given in table 3. Section indicates Killey age for fan delta at Kenai.

Figure A20. Stratigraphy exposed in section 20 (60°33'07"N, 151°14'17"W), Kenai C-4 SE Quadrangle (KEN-53, sheet 2). Chronologic significance of radiocarbon date given in table 2.

Figure A21. Stratigraphy exposed in section 21 (60°32'58"N, 150°59'25"W), Kenai C-3 SW Quadrangle (KEN-56, sheet 2). Tephra geochemistry given in table 3. Section establishes late Killey age for upper local lake deposits on drift of Moosehorn age northeast of Soldotna.

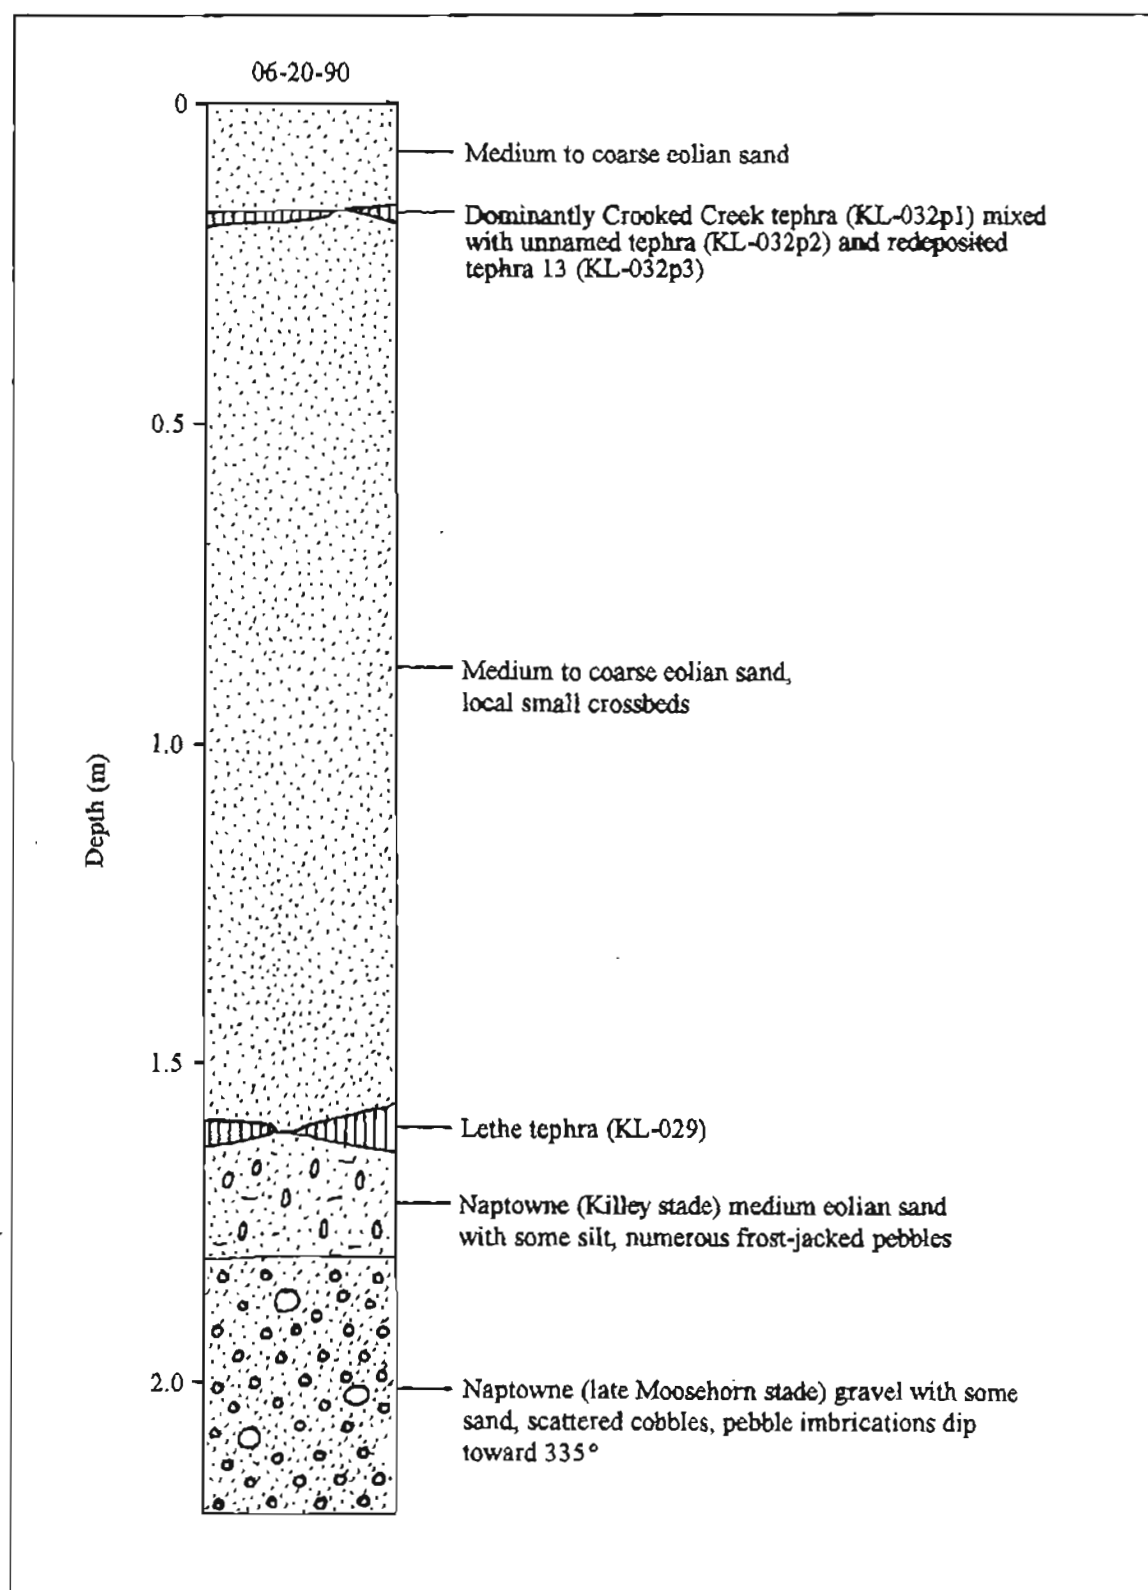

Figure A22. Stratigraphy exposed in section 22 (60°32'50"N, 150°48'17"W), Kenai C-3 SE Quadrangle (KEN-58, sheet 2). Tephra geochemistry given in table 3. Section establishes late Killey age for eolian sand overlying alluvium of late Moosehorn age in meltwater channels west of Moose River.

Figure A23. Stratigraphy exposed in section 23 (60°32'28"N, 151°10'42"W), Kenai C-4 SE Quadrangle (KEN-60, sheet 2). Chronologic significance of radiocarbon dates given in table 2.

Figure A24. Stratigraphy exposed in section 24 ($60^{\circ}32'21''N$, $150^{\circ}49'46''W$), Kenai C-3 SE Quadrangle (KEN-62, sheet 2). Tephra geochemistry given in table 3, except for unnamed tephra complex.

Figure A25. Stratigraphy exposed in section 25 (60°32'13"N, 150°46'15"W), Kenai C-3 SE Quadrangle (KEN-64, sheet 2). Chronologic significance of radiocarbon dates given in table 2. Tephra geochemistry given in table 3, except for unnamed tephra complex.

Figure A26. Stratigraphy exposed in section 26 ($60^{\circ}32'05''\text{N}$, $150^{\circ}44'54''\text{W}$), Kenai C-2 SW Quadrangle (KEN-65, sheet 2). Tephra geochemistry given in table 3, except for unnamed tephra complex. Section indicates Skilak age for slack-water sands on second-highest terrace of Kenai River in Sterling area.

Figure A27. Stratigraphy exposed in section 27 (60°32'04"N, 150°43'53"W), Kenai C-2 SW Quadrangle (KEN-66, sheet 2). Tephra geochemistry given in table 3. Section demonstrates deposition of Lethe tephra after gravel outwash from nearby type Killey moraine.

Figure A28. Stratigraphy exposed in section 28 (60°31'57"N, 150°55'10"W), Kenai C-3 SE Quadrangle (KEN-68, sheet 2). Tephra geochemistry given in table 3, except for unnamed tephra complex. Section establishes late Killey age for dune sand north of Whisper Lake.

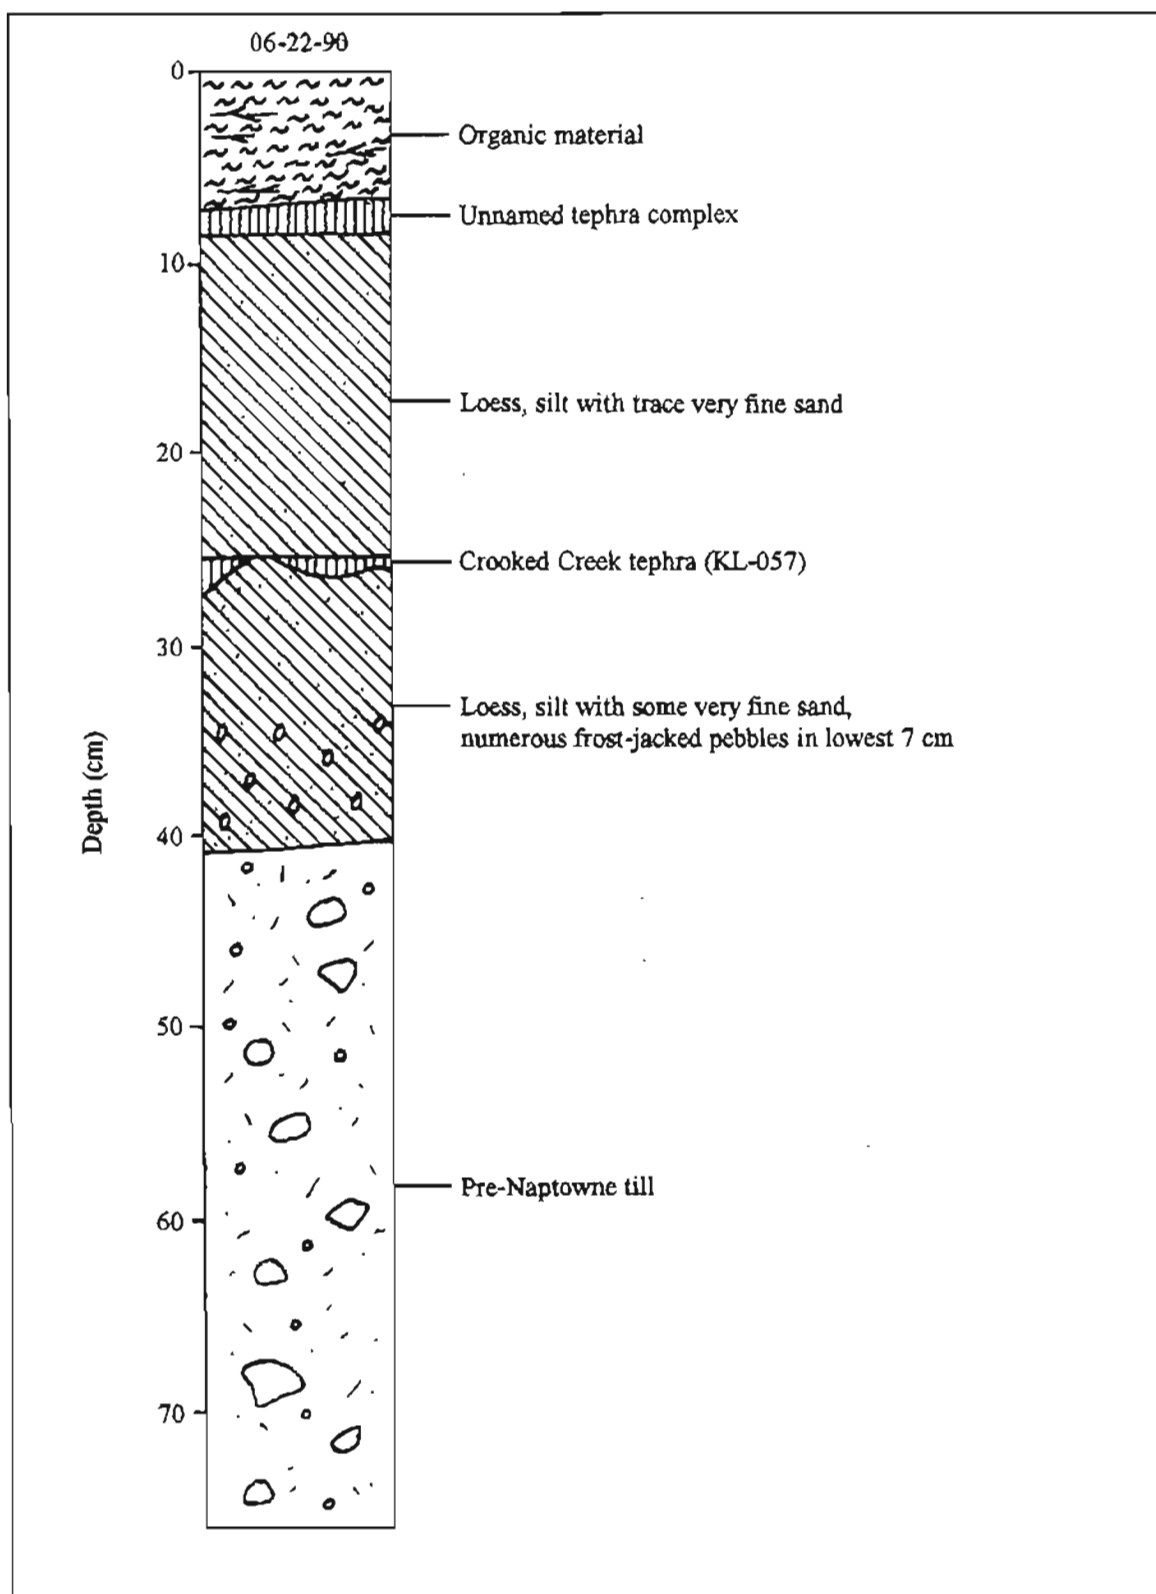

Figure A29. Stratigraphy exposed in section 29 (60°31'49"N, 150°44'01"W), Kenai C-2 SW Quadrangle (KEN-71, sheet 2). Tephra geochemistry given in table 3, except for unnamed tephra complex.

Figure A30. Stratigraphy exposed in section 30A (60°31'30"N, 151°12'31"W), Kenai C-4 SE Quadrangle (KEN-78, sheet 2). Chronologic significance of radiocarbon date given in table 2.

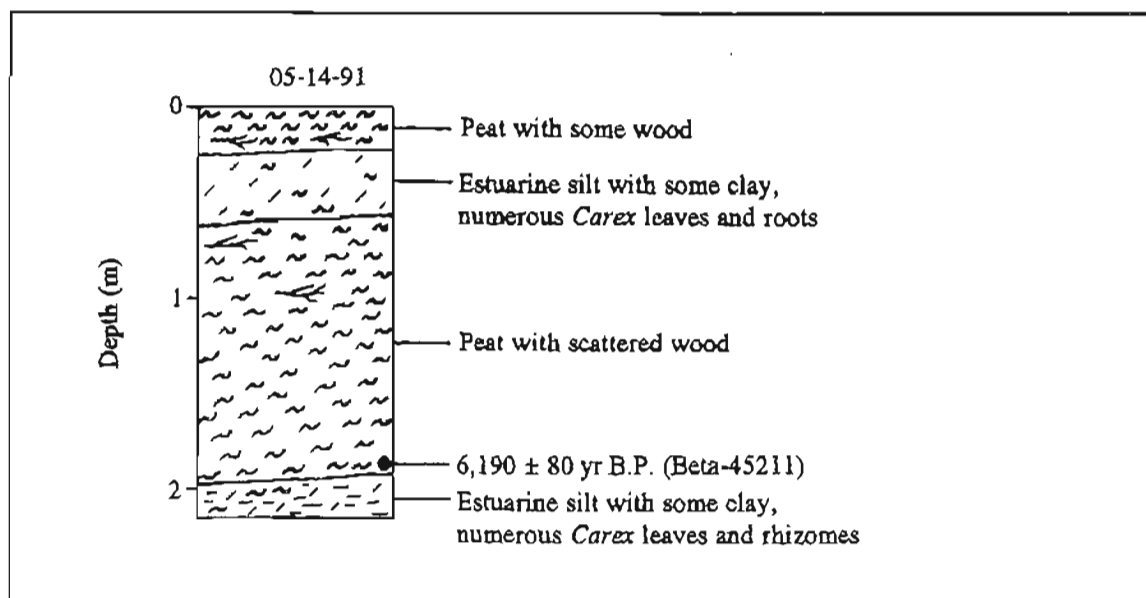

Figure A31. Stratigraphy exposed in section 30B (60°31'30"N, 151°12'31"W), Kenai C-4 SE Quadrangle (KEN-78, sheet 2). Chronologic significance of radiocarbon date given in table 2.

Figure A32. Stratigraphy exposed in section 30C (60°31'30"N, 151°12'31"W), Kenai C-4 SE Quadrangle (KEN-78, sheet 2). Chronologic significance of radiocarbon dates given in table 2.

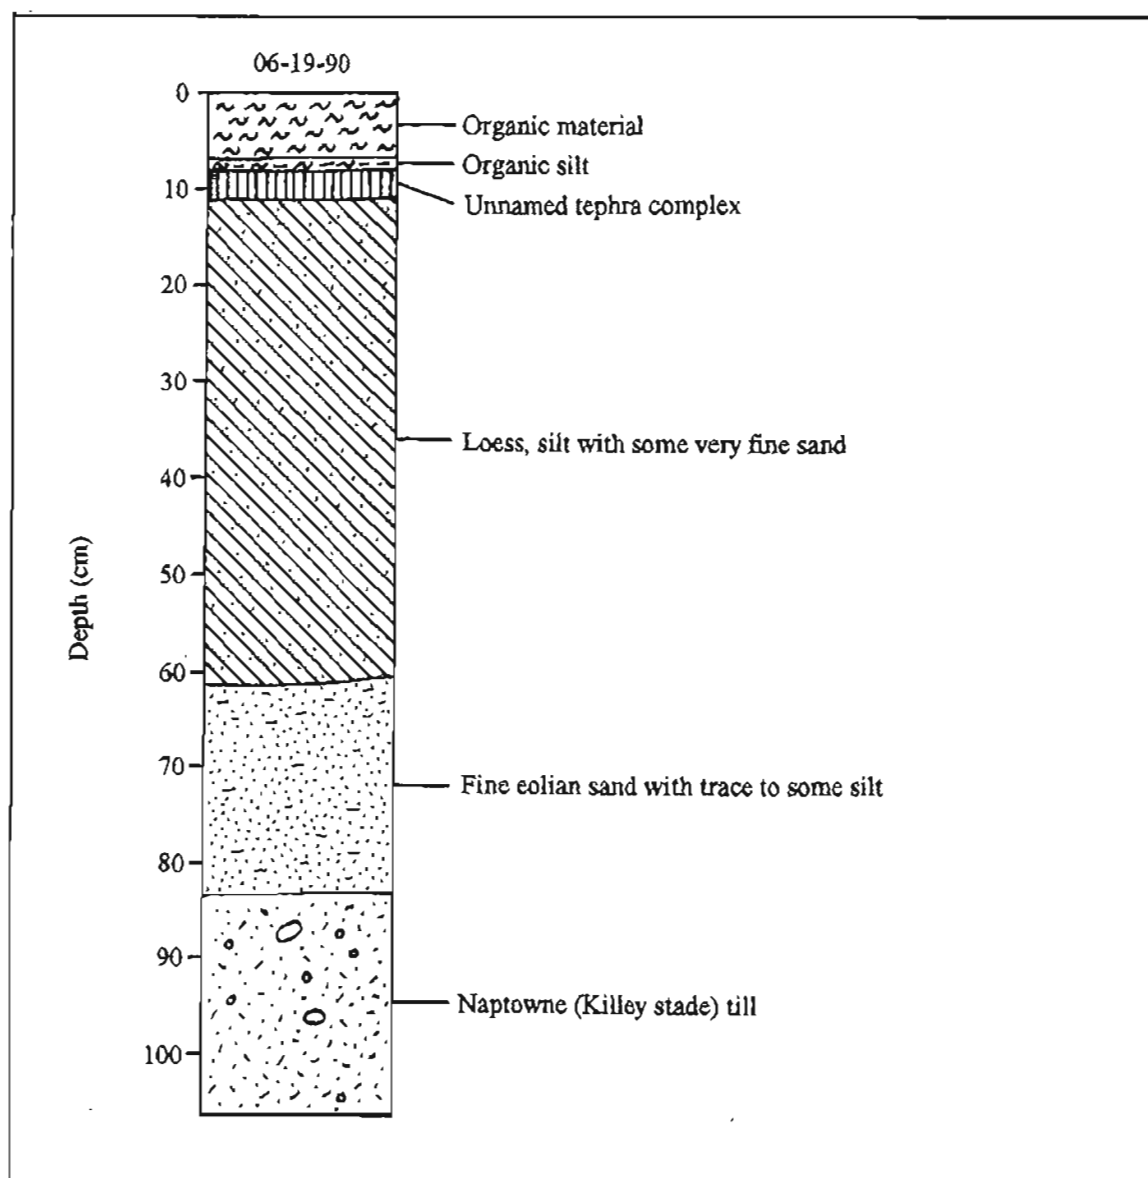

Figure A33. Stratigraphy exposed in section 31 ($60^{\circ}31'25''\text{N}$, $150^{\circ}37'42''\text{W}$) on type Killey moraine, Kenai C-2 SW Quadrangle (KEN-79, sheet 2).

Figure A34. Distribution of silt and clay (calculated as percent of <2-mm fraction) with depth in soil profile S1 on flat crest of type Killey moraine (60°31'25"N, 150°37'42"W), Kenai C-2 SW Quadrangle (KEN-79, sheet 2). Elevation 101 m. Horizons according to Soil Survey Staff (1975), modified by Birkeland and others (1991b) and this study. Horizons O and A not shown above horizon E. Detailed profile description summarized in table A3.

Figure A35. Stratigraphy exposed in section 32 ($60^{\circ}31'23''N$, $150^{\circ}42'34''W$) on type Moosehorn moraine, Kenai C-2 SW Quadrangle (KEN-80, sheet 2).

Figure A36. Distribution of silt and clay (calculated as percent of <2-mm fraction) with depth in soil profile S2 on flat crest of type Moosehorn moraine ($60^{\circ}31'23''\text{N}$, $150^{\circ}42'34''\text{W}$), Kenai C-2 SW Quadrangle (KEN-80, sheet 2). Elevation 91 m. Horizons according to Soil Survey Staff (1975), modified by Birkeland and others (1991b) and this study. Horizon O not shown above horizon A. Detailed profile description summarized in table A4.

Figure A37. Stratigraphy exposed in section 33 (60°31'23"N, 150°40'38"W), Kenai C-2 SW Quadrangle (KEN-81, sheet 2). Chronologic significance of radiocarbon date given in table 2.

Figure A38. Stratigraphy exposed in section 34 (60°31'13"N, 150°53'13"W), Kenai C-3 SE Quadrangle (KEN-82, sheet 2). Tephra geochemistry given in table 3, except for unnamed tephra complex. Section establishes late Killey age for loess overlying ice-stagnation deposits of Moosehorn age near Whisper Lake.

Figure A39. Stratigraphy exposed in section 35 ($60^{\circ}31'06''N$, $150^{\circ}47'45''W$), Kenai C-3 SE Quadrangle (KEN-83, sheet 2). Tephra geochemistry given in table 3.

Figure A40. Stratigraphy exposed in section 36 ($60^{\circ}30'58''N$, $150^{\circ}45'30''W$), Kenai C-3 SE Quadrangle (KEN-85, sheet 2). Tephra geochemistry given in table 3. Section demonstrates deposition of Lethe tephra after gravel outwash from nearby type Killey moraine.

Figure A41. Stratigraphy exposed in section 37 (60°30'57"N, 150°38'48"W), Kenai C-2 SW Quadrangle (KEN-86, sheet 2). Tephra geochemistry given in table 3. Section establishes late Killey age for pond sediments on type Killey moraine.

Figure A42. Stratigraphy exposed in section 38 (60°30'55"N, 150°40'51"W), Kenai C-2 SW Quadrangle (KEN-87, sheet 2). Tephra geochemistry given in table 3. Section demonstrates deposition of Lethe tephra after gravel outwash from the type Killey moraine.

Figure A43. Stratigraphy exposed in section 39 ($60^{\circ}30'41''\text{N}$, $151^{\circ}16'18''\text{W}$), Kenai C-4 SE Quadrangle (KEN-88, sheet 2). Tephra geochemistry given in table 3, except for unnamed tephra complex.

APPENDIX B

Multivariate analysis of magnetic susceptibility and pebble compositions of till samples from the Cook Inlet region.

Rationale

The last major glaciation in the Cook Inlet trough was complicated by glacial advances from several upland sources. Our model of the Naptowne glaciation evolved primarily from the study of landform distribution and interrelations and from stratigraphic evidence. To test its validity, we collected 107 till samples and 92 collections of till pebbles to provide the basic data for an evaluation that is independent of the evidence on which our model is built. We reasoned that the magnetic susceptibility of the fine fractions of the till samples (table 15) and the compositions of the till stones (table 16) reflect rock types in the source areas of the glaciers that deposited the tills. Many of these samples came from tills that have known sources because they are located at the mouths of glaciated valleys or in moraines with distributions that clearly indicate they came from a given source. However, many of the samples came from the central lowlands, where topography is complex and till source is questionable, and we hoped that this experiment would ultimately provide us with new information to fine tune our proposed glaciation model.

Realizing that our data set is probably not large enough to be conclusive for an area so large and complex, we asked Dan Hawkins to develop through multivariate analysis an appropriate numerical scheme that will accurately predict sources of tills in the Cook Inlet region. However, if proven reliable, even to a limited degree, the numerical routine could provide the basis for future sampling and testing efforts that are diagnostic. Multivariate programs that were initially considered for testing include CHAID (a program of automatic interaction detection through classification and regression trees), MDA (multiple discriminant analysis), and AIM (abductive inference mechanism). Also considered was a logistic regression program (LOGIT or PROBIT), but Hawkins (oral commun., 1995) did not believe that the results would differ significantly from the CHAID results. This appendix summarizes the results of the tests conducted by Hawkins (written commun., 1995).

CHAID analysis of the paired-data set

CHAID formulates algorithms for partitioning a given data set into mutually exclusive subsets that best characterize the dependent variables and assigns the statistical significance of these rules. The strengths of this program are: (a) it does not favor one type of independent variable, (b) it does not favor simple partitioning rules, and (c) it does not limit the values assigned to variables with multiple categories (Biggs and others, 1991). The data set that was partitioned by CHAID consists of 10 independent variables, including magnetic-susceptibility measurements of six size fractions of till matrix (ranging from coarse silt to very coarse sand) and counts of four compositional

classes of till pebbles. These independent variables were tested as predictors of the till source (dependent variable), of which there are six sources identified by the proposed model of glaciation in the Cook Inlet region (Reger and Pinney, 1995). Among the 107 till samples and the 92 pebble collections, both magnetic-susceptibility and pebble samples were collected at 85 localities.

CHAID analysis began by initially dividing the data set into two groups. The first group consisted of 54 paired samples that are confidently predicted by the proposed glaciation model to be derived from given sources because they were collected from unambiguous locations. A second group of paired samples ($n = 31$) of questionable derivation came from locations where the likelihood is high that the samples include sediments from more than one source. The group of samples representing proposed known sources was next randomly split in half to form a training or analysis subset (table B1), which CHAID then used to develop two decision trees that incorporate algorithms to predict the source of each paired sample at the 99- and 95-percent confidence levels (table B2).

Predictions of till sources by the proposed glaciation model were matched by CHAID predictions in a significant number of samples at both the 99- and 95-percent confidence levels (table B3). However, the level of correspondence is different in each of the three subsets evaluated.

Matching predictions (99-percent confidence level)

In the training subset, all 27 CHAID predictions matched the sources predicted by the proposed model (table B4A). However, of three possible matching choices, unambiguous assignments were made only for the five samples from the west side of Cook Inlet. Samples from Matanuska Valley ($n = 4$), Chugach Mountains ($n = 5$), and Kenai Mountains ($n = 8$) were all categorized as the more likely of two possible matching choices. There was a less clear response for samples from Talkeetna Mountains ($n = 3$) and Turnagain Arm ($n = 2$), which were

Table B1. *Composition of CHAID training subset of samples representing known till sources predicted by the proposed glaciation model in the Cook Inlet region*

<u>Model source</u>	<u>Number of samples</u>	<u>Percent</u>
Talkeetna Mountains	3	11.1
Matanuska Valley	4	14.8
Chugach Mountains	5	18.5
Turnagain Arm	2	7.4
Kenai Mountains	8	29.6
West side of Cook Inlet	5	18.5
TOTAL	27	99.9

Table B16. Matching of till sources predicted by the proposed glaciation model in the Cook Inlet region and sources predicted by CHAID at the 99-percent confidence level in two data subsets, based on the metasediment-pebble content of 85 pebble collections**A. Known-source subset**

Source area predicted by proposed glaciation model	One CHAID match of two possible choices ^a		One CHAID match of three possible choices ^a			No matching prediction	Total

incorporated during development of the model. For this purpose, the set of magnetic-susceptibility and pebble-lithology data from tills in the eastern and northern Cook Inlet region was evaluated as a predictor of till source areas by four multivariate-analysis techniques. This data set was successfully partitioned to indicate six different till sources. The best partitioning was accomplished by CHAID, which established algorithms to classify source

areas at the 99- and 95-percent confidence levels. Parameters chosen by CHAID as significant predictors include magnetic susceptibility of coarse- and very fine sand fractions of the till matrix and contents of metasediment and plutonic pebbles.

These recommendations were reinforced by the three other analyses. Although our MDA was flawed because its multivariate requirements are violated by the small data set, it clearly demonstrated the importance of metasediment and plutonic pebbles as source indicators. Limiting CHAID analysis to pebble lithologies also demonstrated the importance of metasediment pebbles. Analysis using AIM, although inconclusive, identified three significant parameters as magnetic susceptibility of the very fine sand fraction and the contents of metasediment and plutonic pebbles.

Disparities between predictions of sources by the proposed model and predictions by CHAID and MDA are most obvious and consistent in subsets of samples related by the model to Kenai Mountains and the Aleutian Range west of Cook Inlet. The magnitude of disparity is directly related to the lack of confidence in model assignments. These relations indicate that the proposed glaciation model should be reexamined, particularly in areas where samples of questionable derivation are concentrated.

this classification method compared to CHAID analysis of magnetic susceptibility and pebble lithology. Apparent confirmation of the proposed glaciation model by overwhelming agreement of source predictions (84 of 85 samples) should be tempered with caution because the number of possibly matching categories (five) greatly exceeds the single mismatch category.

AIM analysis

AIM is an artificial intelligence program that uses networks of interconnected nodes, each of which performs a simple computation (Lewinson, 1993). In abductive networks, these computations differ considerably among network nodes, and elaborate mathematical operations are possible. This technique searches for hidden relationships in data sets by building elaborate models that mimic the

data sets. In complex sets of multiple independent and dependent variables, AIM automatically programs network solutions to minimize differences between expected and derived outputs. Through graphic displays, significant variables are identified.

AIM could not produce a decision rule that successfully partitions our data set and identifies discrete sources of tills in the Cook Inlet region. However, it did identify three factors as significant for partitioning: (a) 4- Φ magnetic susceptibility, (b) metasediment-pebble content, and (c) plutonic-pebble content. Thus, it supports the results of CHAID analysis of the paired-data set.

Summary

The purpose of this multivariate analysis was to test the proposed glaciation model using evidence that was not

the four lithologies included in the pebble-count data. This appraisal was limited to the 85 pebble collections in the set of paired data that was originally evaluated by CHAID (table B13). Using five algorithms, CHAID produced a decision tree that partitions the pebble-count data set and discriminates all six source areas at the 99-percent confidence level (table B14). Among the four classes of lithology, metasediment content was judged the only characteristic to be a significant predictor of till sources in the eastern and northern Cook Inlet region.

Comparison of CHAID classifications of paired samples (magnetic susceptibility and pebble counts) and strictly lithologic data indicates that source areas are less clearly differentiated using only lithologic data. Instead of identifying one clear choice or two possibly matching choices of source area as it did with the paired samples (table B3), CHAID used lithologic data to identify either two or three choices of source for every sample (table B15).

In the known-source subset ($n = 58$), there were no predictions where model and CHAID sources disagree, provided that all five possible matching choices are included (table B16A). The most frequently selected CHAID match was in the category of most likely of three possible matching choices (37 of 58 samples). The four other options were chosen about equally.

In the questionable-source subset ($n = 35$), only one sample, which the model attributed to the west side of Cook Inlet, was not matched by one of five possibly matching CHAID choices (table B16B). The dominant choice among the possibly matching choices was in the category of more likely of two possible matching choices (23 of 35 samples).

In summary, CHAID analysis of pebble data supports the MDA conclusion that metasediment pebble content is a significant indicator of till source in the eastern and northern Cook Inlet region. However, limiting CHAID analysis only to pebble lithology blunted the sensitivity of

Figure B1. Ternary diagram of metasediment, quartz, and plutonic percentages in 85 pebble collections from tills in the Cook Inlet region.

MDA mismatches

In the subset of till samples that the proposed model confidently assigns to source areas, many samples "known" to be derived from Kenai Mountains were instead assigned by MDA to Turnagain Arm (10 samples), Chugach Mountains (three samples), and Matanuska Valley (one sample) (table B12A). Of 11 samples "known" to come from the west side of Cook Inlet, MDA assigned six to the Talkeetna Mountains, four to Matanuska Valley, and one to Chugach Mountains.

In the subset of samples assigned with some uncertainty to source areas by the proposed model, there was the greatest disparity with MDA predictions among the samples expected to come from west of Cook Inlet. Of this group, MDA classified 12 samples as being of Chugach Mountains origin, seven samples were related to Matanuska Valley, and two samples were attributed to Talkeetna Mountains (table B12B). One Kenai Mountains sample was assigned by MDA to Matanuska Valley and one to Turnagain Arm. One unique sample from the Matanuska Valley "interlobate area" was related by MDA to the west side of Cook Inlet.

MDA summary

Thus, although flawed because its basic requirements are not satisfied by our small data set, MDA clearly demonstrates that the percentages of metasediment and plutonic lithologies in till pebble collections are significant indicators of till sources in the eastern and northern Cook Inlet region. Once again, however, subtle differences in lithology among the six source areas could not be reliably distinguished in the existing data set.

There are more differences in predictions of till sources by the proposed model and by MDA in the subset of samples that are questionably assigned by the model to given sources. In both subsets these differences are concentrated in samples classified by the model as tills containing lithologies typical of Kenai Mountains and the mountains west of Cook Inlet. Thus, MDA supports the results of the CHAID analysis of the paired samples.

CHAID analysis of pebble data

Once the MDA results became known, we decided to use CHAID to further evaluate the relative significance of

Table B8. Number of pebble collections in two subsets related to till sources predicted by the proposed glaciation model in the Cook Inlet region

West side of Cook Inlet?	25	71.4
TOTAL	35	100.0

In the MDA, discriminant (D) scores, which were produced by six linear discriminant functions that incorporate the percentages of quartz, plutonic, and metasediment pebbles in a pebble collection, are used to predict six corresponding glacier sources as proposed by our model (table B9). For a given pebble collection, the largest discriminant score is the basis for assigning the sample to a particular source. In cases where D scores are close, further calculations can produce more definitive discriminant probabilities, but these calculations are beyond the scope of the present study. MDA algorithms improve our ability to predict source areas 34.8 percent over totally random selection procedures.

MDA indicates that percentages of both metasediment and plutonic pebbles are highly significant (F-probability

= 0.0000) as predictors of till sources, and quartz content is less significant (F-probability = 0.0104). Metasediment-pebble content (F-value = 12.76) is a slightly better indicator than plutonic-pebble content (F-value = 10.33). Combined metasediment and plutonic percentages account for about 70 percent of the within-group variance in the data set. These relationships are clarified when the three parameters are plotted in a ternary diagram (fig. B1). The concentration of data points along the M-P side of the triangle demonstrates the obvious dominance of metasediment and plutonic contents as classifiers of each pebble collection. Relative to these parameters, quartz-pebble content is quite insignificant.

Table B10 compares till sources predicted by the proposed glaciation model and sources predicted by MDA. Of the 92 MDA predictions made, only 42 (45.7 percent) correspond to sources identified by the proposed model (table B11).

MDA matches

In the subset of till samples (n = 55) confidently related to source areas in the proposed model, 29 (54.4 percent) of the MDA predictions matched modeled predictions (table B11A). There was complete agreement for samples from Talkeetna Mountains (n = 3), Matanuska Valley (n = 4), and Turnagain Arm (n = 2). Of six samples modeled to come from Chugach Mountains, five were assigned by MDA to that source. MDA was less successful in matching model predictions of till samples from Kenai Mountains (five of 19 samples) and the west side of Cook Inlet (10 of 21 samples).

In the subset of till samples (n = 35) questionably related to sources in the proposed model, only 11 MDA predictions matched modeled sources (table B11B). Of these, the greatest coincidence exists for samples from the Matanuska Valley "interlobate area" (six of seven samples). Only one of three samples was assigned by MDA to the Kenai Mountains, and only six of 27 samples were related to the west side of Cook Inlet.

Table B9. Linear discriminant functions produced by multiple discriminant analysis of 92 pebble collections to predict till sources in the Cook Inlet region

<u>Source area</u>	<u>Linear discriminant function^a</u>
Talkeetna Mountains	$D_{21} = 1.77X_1 + 0.73X_2 + 0.48X_3 - 32.35$

Multiple discriminant analysis

For a set of data consisting of several independent and dependent variables, multiple discriminant analysis (MDA) develops a series of classification rules (algorithms) that maximizes the between-group variance and minimizes the within-group variance (Hair and others, 1995). Basic requirements of this procedure are: (a) there must be a large number of observations (≥ 20) for each subset and (b) the number of observations must be about equal in every subset. Normally, in MDA each data set is randomly divided into two groups: (a) the analysis sample, which is used to develop the prediction or classification algorithms and (b) the verification or holdout sample, which is used to test the discriminant functions. Ideally, the sizes of both samples should be equal.

Once again, our data set initially incorporated 10 independent variables, including six classes of magnetic-susceptibility measurements (107 samples) and four classes of pebble lithologies ($n=92$), which we wanted to evaluate as indicators of the six glacier source areas (dependent variables) that are predicted by our proposed glaciation model. Because of the small number of samples, the entire data set was used as an analysis sample from

which the classification rules were developed. The lack of a separate verification sample against which the partitioning algorithms could be tested does not necessarily invalidate the results, but means that the results are less reliable than they seem to be (Hair and others, 1995, p. 196).

In an initial phase, stepwise MDA successfully partitioned the full set and clearly identified pebble lithologies as the important indicator of former glacier sources. In contrast to the CHAID results, MDA rejected magnetic susceptibility as an important parameter. Therefore, during subsequent steps, only pebble-count data were analyzed.

The set of pebble-count data consists of nine small subsets that were identified with different degrees of confidence by the proposed model (table B8). In sample subsets "known" by the model to be derived from six sources, the degrees of freedom vary from one to 22. In sample subsets questionably assigned by the model to given sources, the degrees of freedom range from two to 24. Therefore, small sample size and lack of an equal number of samples in each subset are serious impediments for MDA, but we hoped that this approach, even if flawed, would support the results of the CHAID analysis and provide valuable insights about our proposed model of glaciation in the Cook Inlet region.

matched and almost all of these (seven samples) were single choices (table B5B). Of 11 samples "known" by the proposed model to come from Kenai Mountains, seven (63.6 percent) were assigned by CHAID to other sources and, of 15 samples predicted by the model to contain lithologies of the Aleutian Range west of Cook Inlet, 12 (80.0 percent) were assigned to other sources.

In the subset representing till samples of questionable derivation in the proposed model, two samples each from the Matanuska Valley "interlobate area" and Kenai Mountains? were related by CHAID to the appropriate sources as the more likely of two possibly corresponding choices (table B5C). Of 31 samples in this subset, 27 (87.1 percent) of the CHAID predictions did not match sources identified by the proposed glaciation model. Especially notable is the lack of agreement for all 22 samples predicted by the model to originate west of Cook Inlet.

CHAID mismatches (99-percent confidence level)

Of 16 samples in the known-source subset that were classified by CHAID differently than the proposed glaciation model, there is a wide range of mismatches (table B6A). Of four till samples "known" to be derived from Kenai Mountains, three samples were attributed to either Chugach Mountains or Turnagain Arm and one sample was attributed to the west side of Cook Inlet. Among 12 samples from moraines confidently predicted by the proposed model to be built by glaciers flowing southeastward from the Aleutian Range, five (41.7 percent) were assigned by CHAID to either Talkeetna Mountains or Matanuska Valley, three (25.0 percent) were classified as either Talkeetna Mountains or Kenai Mountains samples, three (25.0 percent) were attributed to either Chugach Mountains or Turnagain Arm, and one sample (8.3 percent) was predicted by CHAID to come from either Turnagain Arm or Kenai Mountains.

Of five samples in the questionable-source subset proposed by the model to come from Matanuska Valley "interlobate area," four samples were assigned by CHAID to either Talkeetna Mountains or Kenai Mountains and one sample was attributed to the west side of Cook Inlet (table B6B). Among 22 samples questionably assigned by the proposed model to the west side of Cook Inlet, 15 samples (68.2 percent) were classified by CHAID as samples from either Chugach Mountains or Turnagain Arm, three samples (25.9 percent) were assigned to either Talkeetna Mountains or Kenai Mountains, two samples (9.1 percent) were classified as either Talkeetna Mountains or Matanuska Valley samples, and two samples were attributed to either Turnagain Arm or Kenai Mountains.

CHAID mismatches (95-percent confidence level)

As expected, at the 95-percent confidence level, there

are more differences in assignments of till sources by the proposed glaciation model and by CHAID than at the 99-percent confidence level (table B7).

In the subset of samples confidently assigned by the model to the Kenai Mountains, CHAID unambiguously assigned four to Turnagain Arm, two to Chugach Mountains, and one to the Aleutian Range west of Cook Inlet (table B7A). CHAID was less forceful in its assignments of 12 till samples modeled to be derived from the west side of Cook Inlet. Only two samples were unambiguously attributed to Matanuska Valley and one sample was clearly assigned to Chugach Mountains. Among the other nine samples, three each were assigned to either Talkeetna Mountains or Kenai Mountains and either Chugach Mountains or Turnagain Arm, two were classified as samples from either Talkeetna Mountains or Matanuska Valley, and one was attributed to either Turnagain Arm or Kenai Mountains.

In the subset of till samples questionably related to glacial sources by the model, among five samples from the Matanuska Valley "interlobate area," CHAID unambiguously classified one as a till from the west side of Cook Inlet and assigned the other four samples to either Talkeetna Mountains or Kenai Mountains (table B7B). Of 22 till samples tentatively related to the west side of Cook Inlet by the proposed glaciation model, only one sample was clearly assigned by CHAID to the Chugach Mountains. More ambiguous assignments were made for 15 samples to either Chugach Mountains or Turnagain Arm, three samples to either Talkeetna Mountains or Kenai Mountains, two samples to either Talkeetna Mountains or Matanuska Valley, and one sample to either Turnagain Arm or Kenai Mountains.

Summary of CHAID analysis

Differences in predictions by the proposed glaciation model and by CHAID correspond to our confidence in the proposed model. Partitioning was perfect in the training subset ($n = 27$), in which the origin of the samples is unambiguous in the proposed model. Clearly, the training subset is statistically significant. Fewer CHAID predictions matched model sources in the equally large split of samples ($n = 27$) that are slightly less confidently attributed to given sources in the model. The greatest disparity between model and CHAID sources is present in the subset ($n = 31$) of questionable samples. In all three subsets, disparities between predictions of till source by the proposed model and by CHAID most notably involved samples attributed by the model to Kenai Mountains and the west side of Cook Inlet. These consistent trends indicate that the proposed model should be reexamined. Sample size is apparently not a factor influencing CHAID performances with the three subsets.

^aIncludes both known and questionable till sources.

^b1 = Talkeetna Mountains, 2 = Matanuska Valley, 2? = Matanuska Valley "interlobate area," 3 = Chugach Mountains, 4 = Turnagain Arm, 5 = Kenai Mountains, 6 = west side of Cook Inlet.

^cThe numerical pair 5,4 means that the predicted source is 85.7 percent likely to be 5, based on group composition in the selected subset (table B2).

^dThe numerical pair 3,4 means that the predicted source is 83.3 percent likely to be 3, based on group composition in the selected subset (table B2).

^eThe numerical pair 5,1 means that the predicted source is 66.7 percent likely to be 5, based on group composition in the selected subset (table B2).

^fThe numerical pair 2,1 means that the predicted source is 66.7 percent likely to be 2, based on group composition in the selected subset (table B2).

samples predicted by the proposed model to have been deposited by the Trading Bay lobe that spread southeastward across Cook Inlet were assigned by CHAID to other sources.

Matching predictions (95-percent confidence level)

In the training subset, all 27 model predictions were once again matched by CHAID predictions (table B5A). Clear matching assignments were made to all six source

areas for 23 of 27 samples (85.2 percent). Two samples, comprising one quarter of the samples predicted by the model to be of Kenai Mountains derivation, were confirmed by CHAID as the more likely of two possibly matching choices. One sample each from Talkeetna Mountains and Turnagain Arm according to the proposed model were assigned there by CHAID as the less likely of two possibly matching choices.

In the subset representing the other half of the known samples ($n = 27$), only eight of 27 predictions (29.6 percent)

Table B3. Comparison of till sources predicted by the proposed glaciation model and sources predicted by CHAID, based on magnetic-susceptibility measurements of 0- Φ and 4- Φ fractions and percent of metasediment and plutonic pebbles. categorized as the less likely of two possibly matching choices.

In the subset representing the other split of the known-source samples ($n = 27$), single clear assignments were made only for three samples from the west side of Cook Inlet (table B4B). Samples from Chugach Mountains ($n = 1$) and Kenai Mountains ($n = 7$) were confirmed as the more likely of two possibly matching choices. There were no CHAID matches for four samples that the proposed glaciation model predicted came from Kenai Mountains and 12 till samples that the model assigned to the west side of Cook Inlet.

In the subset representing till samples of questionable

derivation according to the proposed model, there were no single clear assignments of source area (table B4C). Two samples collected in the transition zone between till deposited by Matanuska Valley ice and till deposited by ice from Chugach Mountains (herein termed the Matanuska Valley "interlobate area") were assigned by CHAID to either source as the more likely of two possibly matching choices. Two till samples that the model questionably assigned to Kenai Mountains were also assigned there by CHAID as the more likely of two possibly matching choices. Five samples from the Matanuska Valley "interlobate area" were not assigned by CHAID to either the Matanuska Valley or Chugach Mountains, and 22 till
