Geochemical Data of Fumarolically Altered Rocks, Valley of Ten Thousand Smokes, Alaska

by

Terry E. C. Keith[1]

Open-File Report 95-47

[1]Anchorage, Alaska

1995

ABSTRACT

Selected major oxides, volatile elements, and trace elements were analyzed on sets of samples collected from fossil fumaroles in the fallout and ash-flow tuff emplaced during the 6-8 June 1912 eruption of Novarupta. Analytical results are presented in this report and references are given for publications in which the data is interpreted.

INTRODUCTION

The purpose of this report is to present the analytical results of samples from fumarolically altered parts of the ash-flow sheet and overlying fallout deposits from the 6-8 June 1912 eruption of Novarupta (Hildreth, 1983, 1987; Fierstein and Hildreth, 1992) in what is now Katmai National Park. Several papers already published are based on the data in this report (e.g., Keith, 1984, 1991a, 1991b; Kodosky and Keith, 1993, 1995). Papers by Papike and others (1991a, 1991b) include analytical data from some of the same samples but these data were obtained using different analytical techniques.

Samples were collected from ash-flow tuff that was altered by acidic fumarolic gases along vertical vent walls. Trace elements from the altered wallrock combined with the acid gases and were transported to the surface where rapid cooling took place. Minerals and unstable chemical phases sublimated onto clasts in the porous fallout deposits cementing the fallout adjacent to fumarolic vents. These features in the ash-flow sheet are very resistant to weathering and clearly define the fossil fumarole orifices (Keith, 1991a).

The leaching process continued in the fallout deposits at the surface as acid gases combined with surface waters to form sulfuric, hydrochloric and hydrofluoric acids. As the fumaroles cooled and died out, surface waters neutralized the surficial acids and the system equilibrated at the surface. Water soluble and metastable chemical phases and minerals containing abundant trace metals were removed from the system by dissolution in surface waters (Keith, 1991a).

SAMPLE COLLECTION AND NUMBERING

Fist- to golfball-sized samples were collected from exposures of fumarolically altered fallout and ash-flow tuff from selected fossil fumaroles throughout the Valley of Ten Thousand Smokes (VTTS). Each fossil fumarole site was given a number (fig. 1). Samples from each site were given two numbers designating the year collected, KAT for Katmai National Park, and the fossil fumarole site number. Capital letters beginning with A designate the location of the sample with respect to the fumarolic orifice for the site. The letter A signifies a sample very close to the vent, whereas succeeding letters are consecutively away from the vent. Some variances to

this scheme occur because of complex or multiple fumarolic vent geometry and complex alteration patterns. Thus, sample 79KAT-15A was collected in 1979 at Katmai National Park from fossil fumarole site 15 (fig. 1) and is the first in a sequence A through E (tables 1, 2). A few samples were split into subsets with another number following the letter, e.g., 79KAT-15A1.

The major component of most samples is pumice composed of altered to partially altered rhyolite, dacite, or andesite. Phenocrysts in the pumice include small percentages of plagioclase, clinopyroxene, orthopyroxene, and rare olivine (Hildreth, 1983). The specific composition of fumarolically altered ash-flow tuff and fallout depends partly on protolith composition. Rhyolite protolith is abundant in the lower VTTS and scarce in the middle and upper valley, dacite is the major component in the middle and upper VTTS ash-flow sheet and fallout units blanketing the ash-flow sheet, and andesite is more abundant in the Novarupta vent region relative to the rest of the VTTS.

Interpretation of fumarolic alteration and deposition in the 1912 deposits from which the analyzed samples were collected can be found in the papers listed in the references.

CHEMICAL DATA FOR FUMAROLICALLY ALTERED SAMPLES FROM THE VALLEY OF TEN THOUSAND SMOKES

All analyses were done by US Geological Survey (USGS) analysts in Menlo Park, CA and Denver, CO. Many sample splits submitted for analysis were smaller than the desired weight to obtain the best precision, especially some of those run for trace metals.

Major oxides on selected whole-rock samples (table 1) were analyzed using the wavelength-dispersive X-ray fluorescence (XRF) technique described by Taggart and others (1987). Analysts for samples in table 1 were J. Taggart, A. Bartel, E. Siems, J. Ardith, K. Bartel, K. Stewart, J. Carr, and L. Espos.

Analyses of FeO, H_2O^+, H_2O^-, and CO_2 were obtained on most of the same samples for which major oxides were analyzed (table 1). These components are known as the "XRF support package" by USGS because these are the major components which are volatile and listed as Loss on Ignition (LOI) in the XRF analysis. Techniques used for the VTTS samples are described by Jackson and others (1987). Analysts were T. Fries, S. Pribble, and S. Neil.

Cl, F, and total sulfur content of selected whole-rock samples were also run (table 1) using techniques described by Jackson and others (1987). Analysts were N. Elsheimer, S. MacPherson, G. Mason, J. Graves, and E. Engleman.

Semiquantitative emission spectrographic analyses for many samples (table 2) were done to determine relative depletions and enrichments of trace elements within fumarolic deposits. Techniques used are given in Golightly and others (1987), however, modifications were made to these techniques in order to attain lower limits of detection of some elements. The analyst for all

samples was C. Heropoulos, except those from sites 113 and 127 which were done by R. Lerner. Many of the samples were reanalyzed for chalcophile elements (As, Au, Bi, Cd, P, Te, Tl, Sb, Se, Zn, Hg) by C. Heropoulos using a short-wave radiation (SWR) technique which he adapted to obtain more precise values on small samples with low chalcophile element contents.

The following elements were sought using semiquantitative emission spectrographic analyses but were not found at the given limit of detection (in parts per million [ppm]): Ce (<50), Pd (<1), Pt (<5), Te (<1 by SWR), and U (<150). Semiquantitative spectrographic analysis includes Si, Al, Na, K, P, Fe, Mg, Ca, and Ti (in weight percent) and for Mn (in ppm) (table 2). Better analyses for these elements were obtained as major oxides by the XRF method (table 1), however, since many samples were not analyzed for major oxides, the semiquantitative spectrographic analytical results are included in table 2.

Limits of detection for semiquantitative emission spectrographic analysis are given in Golightly and others (1987). However, because of variations in the techniques used for the analyses in table 2, the limit of detection is given by less than (<) followed by the value. For samples from a given site, N means a particular element was not detected at the limit of detection heading that column. For example, Nb for site 15 has limit of detection of 10 ppm, so the first sample in the Nb column is given as N <10 ppm with following samples showing N, which means 10 ppm is the lower limit of detection for Nb in all the site 15 samples. Sample 79KAT-15E, however, shows a Nb value of 7 ppm because a larger sample was available for analysis and a lower limit of detection could be attained. Some of the limits of detection for the same element in a series of samples from a single fumarole site may be different because of sample size, e.g., for sample 82KAT-127A Mn is < 400 ppm but for 82KAT-127B Mn is 350 ppm; the difference being that 127A was a very small amount of sample. (Remember, all of these results are semiquantitative!)

Table 2. Trace element analyses for whole-rock samples of fumarolically-altered ash-flow tuff and fallout from the 1912 eruption of Novarupta. Values in parts per million (ppm) unless otherwise indicated. See text for analysts and methods. N = not detected at limit of detection given for first sample in series (see text), SWR = analyzed by short-wave radiation technique (see text), H = interference, usually by high Fe or organic material.
